- Standard output and standard error are normally written to a location such as `/var/spool`, then copied to their final location. To avoid creating these files at all, and to avoid copying them, use direct write to send them to `/dev/null`:  
`qsub -koed -o /dev/null -e /dev/null`

Your administrator must also set up the MoM’s configuration file to support this.

## 3.3.4 Merging Output and Error Files

By default, PBS creates separate standard output and standard error files for each job. You can specify that `stdout` and `stderr` are to be joined by setting the job’s `Join_Path` attribute. The default for the attribute is `n`, meaning that no joining takes place. You can set the attribute using the following methods:

- Use `qsub -j <joining option>`
- Use `#PBS Join_Path=<joining option>`

You can specify one of the following *joining options*:

`oe`

Standard output and standard error are merged, intermixed, into a single stream, which becomes standard output.

**eo**

Standard output and standard error are merged, intermixed, into a single stream, which becomes standard error.

**n**

Standard output and standard error are not merged.

For example, to merge standard output and standard error for `my_job` into standard output:

```
qsub -j oe my_job
#PBS -j oe
```

### 3.3.5 Keeping Output and Error Files on Execution Host

By default, PBS copies `stdout` and `stderr` to the job's submission directory. You can specify that PBS keeps `stdout`, `stderr`, or both in the job's execution directory on the execution host. This behavior is controlled by the job's `Keep_Files` attribute. You can set this attribute to one of the following values:

**e**

PBS keeps `stderr` in the job's staging and execution directory on the primary execution host.

**o**

PBS keeps `stdout` in the job's staging and execution directory on the primary execution host.

**eo, oe**

PBS keeps both standard output and standard error on the primary execution host, in the job's staging and execution directory.

**n**

PBS does not keep either file on the execution host.

**d**

PBS writes both `stdout` and `stderr` to their final destinations. Overrides `o` and `e` options. See [section 3.3.6, “Writing Files Directly to Final Destination”, on page 45](#).

The default value for `Keep_Files` is “`n`”.

You can set the value of the `Keep_Files` job attribute using the following methods:

- Use `qsub -k <keep option>`
- Use `#PBS Keep_Files=<keep option>`

For example, you can use either of the following to keep both standard output and standard error on the execution host:

```
qsub -k oe my_job
#PBS -k oe
```

#### 3.3.5.1 Caveats for Keeping Files on Execution Host

- When a job finishes, its job-specific execution directory, and all files in that directory, are deleted. If you specified that `stdout` and/or `stderr` should be kept on the execution host, any files you specified are deleted as well.
- The `qsub -k` option overrides the `-o` and `-e` options. For example, if you specify `qsub -k o -o <path>`, `stdout` is kept on the execution host, and is not copied to the path you specified.

### 3.3.6 Writing Files Directly to Final Destination

If the MoM on the primary execution host can reach the final destination, she can write the job's standard output and standard error files to that destination. To be reachable, the final destination host and path must either be on the execution host, or be mapped from the primary execution host via the `$usecp` directive in the MoM configuration file. To specify that standard output and/or standard error should be written directly to their final destinations, use the `d` sub-option to the `-k` option to `qsub` or `qalter`.

For example, to directly write both output and error to their final destinations:

```
qsub -koed job.sh
```

To directly write output to its final destination, and let error go through normal spooling and staging:

```
qsub -kod job.sh
```

### 3.3.7 Changing Linux Job `umask`

On Linux, whenever your job copies or creates a file or directory on the execution host, MoM uses `umask` to determine the permissions for the file or directory. If you do not specify a value for `umask`, MoM uses the system default. You can specify a value using the following methods:

- Use `qsub -W umask=<value>`
- Use `#PBS umask=<value>`

This applies when staging or copying files or directories to the execution host, or writing `stdout` or `stderr` on the execution host.

In the following example, we set `umask` to `022`, to have files created with write permission for owner only. The desired permissions are `-rw-r--r--`.

```
qsub -W umask=022 my_job
#PBS -W umask=022
```

#### 3.3.7.1 Caveats

This feature does not apply to Windows.

### 3.3.8 Troubleshooting File Delivery

File delivery is handled by MoM on the execution host. For a description of how file delivery works, see ["Setting File Transfer Mechanism" on page 549 in the PBS Professional Administrator's Guide](#).

For troubleshooting file delivery, see ["Troubleshooting File Transfer" on page 554 in the PBS Professional Administrator's Guide](#).

---

### 3.3.8.1 Non-delivery of Output

If the output of a job cannot be delivered to you, it is saved in a special directory named `PBS_HOME/undelivered` and mail is sent to you. The typical causes of non-delivery are:

1. The destination host is not trusted and you do not have a `.rhosts` file.
2. An improper path was specified.
3. A directory in the specified destination path is not writable.
4. Your `.cshrc` on the destination host generates output when executed.
5. The path specified by `PBS_SCP` in `pbs.conf` is incorrect.
6. The `PBS_HOME/spool` directory on the execution host does not have the correct permissions. This directory must have mode `1777 drwxrwxrwt` (on Linux) or “Full Control” for “Everyone” (on Windows).

### 3.3.9 Caveats for Output and Error Files

#### 3.3.9.1 Retaining Files on Execution Host

When PBS creates a job-specific staging and execution directory and you use the `-k` option to `qsub` or you specify `o` and/or `e` in the `Keep_Files` attribute, the files you requested kept on the execution host are deleted when the job-specific staging and execution directory is deleted at the end of the job.

#### 3.3.9.2 Standard Output and Error Appended When Job is Rerun

If your job runs and writes to `stdout` or `stderr`, and then is rerun, meaning that another job with the same name is run, PBS appends the `stdout` of the second run to that of the first, and appends the `stderr` of the second run to that of the first.

#### 3.3.9.3 Windows Mapped Drives and PBS

In Windows, when you map a drive, it is mapped locally to your session. The mapped drive cannot be seen by other processes outside of your session. A drive mapped on one session cannot be un-mapped in another session even if the user is the same. This has implications for running jobs under PBS. Specifically if you map a drive, `chdir` to it, and submit a job from that location, the vnode that executes the job may not be able to deliver the files back to the same location from which you issued `qsub`. The workaround is to tell PBS to deliver the files to a local, non-mapped, directory. Use the “`-o`” or “`-e`” options to `qsub` to specify the directory location for the job output and error files. For details see [section 3.3.2, “Paths for Output and Error Files”, on page 42](#).

#### 3.3.9.4 Harmless `csh` Error Message

If your login shell is `csh` the following message may appear in the standard output of a job:

```
Warning: no access to tty, thus no job control in this shell
```

This message is produced by many `csh` versions when the shell determines that its input is not a terminal. Short of modifying `csh`, there is no way to eliminate the message. Fortunately, it is just an informative message and has no effect on the job.

#### 3.3.9.5 Interactive Jobs and File I/O

When an interactive job finishes, `stdout` and/or `stderr` may not have been copied back yet.

---

### 3.3.9.6 Write Permissions Required

- You must have write permission for any directory where you will copy `stdout` or `stderr`.
- Root must be able to write in `PBS_HOME/spool`.

# Allocating Resources & Placing Jobs

## 4.1 What is a Vnode?

A virtual node, or vnode, is an abstract object representing a set of resources which form a usable part of a machine. This could be an entire host, or a nodeboard or a blade. A single host can be made up of multiple vnodes.

A host is any computer. Execution hosts used to be called nodes, and are still often called nodes outside of the PBS documentation. PBS views hosts as being composed of one or more vnodes.

PBS manages and schedules each vnode independently. Jobs run on one or more vnodes. Each vnode has its own set of attributes; see [“Vnode Attributes” on page 320 of the PBS Professional Reference Guide](#).

### 4.1.1 Deprecated Vnode Types

All vnodes are treated alike, and are treated the same as what were once called “time-shared nodes”. The types “time-shared” and “cluster” are deprecated. The `:ts` suffix is deprecated. It is silently ignored, and not preserved during rewrite.

The vnode attribute `ntype` was only used to distinguish between PBS and Globus vnodes. Globus can still send jobs to PBS, but PBS no longer supports sending jobs to Globus. The `ntype` attribute is read-only.

## 4.2 PBS Resources

### 4.2.1 Introduction to PBS Resources

In this section, [“Introduction to PBS Resources”](#), we will briefly cover the basics of PBS resources. For a thorough discussion, see [“Using PBS Resources” on page 229 in the PBS Professional Administrator’s Guide](#), especially sections [5.4](#) and [5.5](#). For a complete description of each PBS resource, see [Chapter 5, “List of Built-in Resources”, on page 259](#).

PBS resources represent things such as CPUs, memory, application licenses, switches, scratch space, and time. They can also represent whether or not something is true, for example, whether a machine is dedicated to a particular project.

PBS provides a set of built-in resources, and allows the administrator to define additional custom resources. Custom resources are used for application licenses, scratch space, etc., and are defined by the administrator. Custom resources are used the same way built-in resources are used. PBS supplies the following types of resources:

#### Boolean

Name of Boolean resource is a string.

Values:

*TRUE, True, true, T, t, Y, y, 1*

*FALSE, False, false, F, f, N, n, 0*

**Duration**

A period of time, expressed either as

*An integer whose units are seconds*

or

*[[hours:]minutes:]seconds[.milliseconds]*

in the form:

*[[HH:]MM:]SS[.milliseconds]*

Milliseconds are rounded to the nearest second.

**Float**

Floating point. Allowable values: [+ -] 0-9 [[0-9] ...][.][[0-9] ...]

**Long**

Long integer. Allowable values: 0-9 [[0-9] ...], and + and -

*<queue name>@<server name>*

**Size**

Number of bytes or words. The size of a word is 64 bits.

Format: *<integer>[<suffix>]*

where *suffix* can be one of the following:

**Table 4-1: Size in Bytes**

| Suffix   | Meaning                | Size                                  |
|----------|------------------------|---------------------------------------|
| b or w   | Bytes or words         | 1                                     |
| kb or kw | Kilobytes or kilowords | 2 to the 10th, or 1024                |
| mb or mw | Megabytes or megawords | 2 to the 20th, or 1,048,576           |
| gb or gw | Gigabytes or gigawords | 2 to the 30th, or 1,073,741,824       |
| tb or tw | Terabytes or terawords | 2 to the 40th, or 1024 gigabytes      |
| pb or pw | Petabytes or petawords | 2 to the 50th, or 1,048,576 gigabytes |

Default: *bytes*

Note that a scheduler rounds all resources of type *size* up to the nearest kb.

**String**

Any character, including the space character.

Only one of the two types of quote characters, " or ', may appear in any given value.

Values: *[\_a-zA-Z0-9][[-\_a-zA-Z0-9 ! " # \$ % ' ( ) \* + , - . / : ; < = > ? @ [ \ ] ^ \_ ' { | } ~] ...]*

String resource values are case-sensitive. No limit on length.

### String Array

Comma-separated list of strings.

Strings in `string_array` may not contain commas. No limit on length.

Python type is `str`.

A string array resource with one value works exactly like a string resource.

See [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#) for a listing of built-in resources.

For some systems, PBS creates specific custom resources.

The administrator can specify which resources are available at the server, each queue, and each vnode. Resources defined at the queue or server level apply to an entire job. Resources defined at the vnode level apply only to the part of the job running on that vnode.

Jobs can request resources. The scheduler matches requested resources with available resources, according to rules defined by the administrator. PBS always places jobs where it finds the resources requested by the job. PBS will not place a job where that job would use more resources than PBS thinks are available. For example, if you have two jobs, each requesting 1 CPU, and you have one vnode with 1 CPU, PBS will run only one job at a time on the vnode.

PBS can enforce limits on resource usage by jobs; see [section 4.5, “Limits on Resource Usage”, on page 61](#).

## 4.2.2 Glossary

### Chunk

A set of resources allocated as a unit to a job. Specified inside a selection directive. All parts of a chunk come from the same host. In a typical MPI (Message-Passing Interface) job, there is one chunk per MPI process.

### Chunk-level resource, host-level resource

A resource that is available at the host level, for example, CPUs or memory. Chunk resources are requested inside of a selection statement. The resources of a chunk are to be applied to the portion of the job running in that chunk.

Chunk resources are requested inside a select statement.

### Job-wide resource, server resource, queue resource

A job-wide resource, also called a server-level or queue-level resource, is a resource that is available to the entire job at the server or queue.

A job-wide resource is available to be consumed or matched at the server or queue if you set the server or queue `resources_available.<resource name>` attribute to the available or matching value. For example, you can define a custom resource called *FloatingLicenses* and set the server's `resources_available.FloatingLicenses` attribute to the number of available floating licenses.

Examples of job-wide resources are shared scratch space, application licenses, or walltime.

A job can request a job-wide resource for the entire job, but not for individual chunks.

## 4.3 Requesting Resources

Your job can request resources that apply to the entire job, or resources that apply to job chunks. For example, if your entire job needs an application license, your job can request one job-wide license. However, if one job process needs two CPUs and another needs 8 CPUs, your job can request two chunks, one with two CPUs and one with eight CPUs. Your job cannot request the same resource in a job-wide request and a chunk-level request.

PBS supplies resources such as `walltime` that can be used only as job-wide resources, and other resources, such as `ncpus` and `mem`, that can be used only as chunk resources. A resource is either job-wide or chunk-level, but not both. The description of each resource tells you which way to use the resource; see [“List of Built-in Resources” on page 259 of the PBS Professional Reference Guide](#).

We will cover the details of requesting resources in [section 4.3.2, “Requesting Job-wide Resources”, on page 52](#) and [section 4.3.3, “Requesting Resources in Chunks”, on page 53](#).

### 4.3.1 Quick Summary of Requesting Resources

Job-wide resources are requested in `<resource name>=<value>` pairs. You can request job-wide resources using any of the following:

- The `qsub -l <resource name>=<value>` option  
You can request multiple resources, using either format:  
`-l <resource>=<value>,<resource>=<value>`  
`-l <resource>=<value> -l <resource>=<value>`
- One or more `#PBS -l <resource name>=<value>` directives

Chunk resources are requested in *chunk specifications* in a *select statement*. You can request chunk resources using any of the following:

- The `qsub -l select=[N:][<chunk specification>][+[N:]<chunk specification>]` option
- A `#PBS -l select=[N:][<chunk specification>][+[N:]<chunk specification>]` directive

Format for requesting both job-wide and chunk resources:

```
qsub ... (non-resource portion of job)
-l <resource>=<value> (this is the job-wide request)
-l select=<chunk>[+<chunk>] (this is the selection statement)
```

PBS supplies several commands that you can use to request resources or alter resource requests:

- The `qsub` command (both via command-line and in PBS directives)
- The `pbs_rsub` command (via command-line only)
- The `qalter` command (via command-line only)

### 4.3.2 Requesting Job-wide Resources

Your job can request resources that apply to the entire job in *job-wide* resource requests. A job-wide resource is designed to be used by the entire job, and is available at the server or a queue, but not at the host level. Job-wide resources are used for requesting floating application licenses or other resources not tied to specific vnodes, such as `cput` and `walltime`.

Job-wide resources are requested outside of a selection statement, in this form:

```
-l <resource name>=<value>[,<resource name>=<value> ...]
```

A resource request “outside of a selection statement” means that the resource request comes after “`-l`”, but not after “`-lselect=`”. In other words, you cannot request a job-wide resource in chunks.

For example, to request one hour of `walltime` for a job:

```
-l walltime=1:00:00
```

You can request job-wide resources using any of the following:

- The `qsub -l <resource name>=<value>` option

You can request multiple resources, using either format:

```
-l <resource>=<value>,<resource>=<value>
```

```
-l <resource>=<value> -l <resource>=<value>
```

- One or more `#PBS -l <resource name>=<value>` directives

### 4.3.3 Requesting Resources in Chunks

A *chunk* specifies the value of each resource in a set of resources which are to be allocated as a unit to a job. It is the smallest set of resources to be allocated to a job. All of a chunk is taken from a single host. One chunk may be broken across vnodes, but all participating vnodes must be from the same host.

Your job can request chunk resources, which are resources that apply to the host-level parts of the job. Host-level resources can only be requested as part of a chunk. Server or queue resources cannot be requested as part of a chunk. A chunk resource is used by the part of the job running on that chunk, and is available at the host level. Chunks are used for requesting host-related resources such as CPUs, memory, and architecture.

Chunk resources are requested inside a select statement. A select statement has this form:

```
-l select=[N:]<chunk>[+[N:]<chunk> ...]
```

Now, we'll explain the details. A single chunk is requested using this form:

```
-l select=<resource name>=<value>[:<resource name>=<value>...]
```

For example, one chunk might have 2 CPUs and 4GB of memory:

```
-l select=ncpus=2:mem=4gb
```

To request multiples of a chunk, prefix the chunk specification by the number of chunks:

```
-l select=[<number of chunks>]<chunk specification>
```

For example, to request six of the previous chunk:

```
-l select=6:ncpus=2:mem=4gb
```

If you don't specify *N*, the number of chunks, it is taken to be 1.

To request different chunks, concatenate the chunks using the plus sign (“+”):

```
-l select=[<number of chunks>]<chunk specification>+[<number of chunks>]<chunk specification>
```

For example, to request two sets of chunks where one set of 6 chunks has 2 CPUs per chunk, and one set of 3 chunks has 8 CPUs per chunk, and both sets have 4GB of memory per chunk:

```
-l select=6:ncpus=2:mem=4gb+3:ncpus=8:mem=4GB
```

No spaces are allowed between chunks.

You must specify all your chunks in a single select statement.

You can request chunk resources using any of the following:

- The `qsub -l select=[N:]<chunk specification>[+[N:]<chunk specification>]` option
- A `#PBS -l select=[N:]<chunk specification>[+[N:]<chunk specification>]` directive

### 4.3.4 Requesting Boolean Resources

A resource request can specify whether a Boolean resource should be *True* or *False*.

Example 4-1: Some vnodes have `green=True` and some have `red=True`, and you want to request two vnodes, each with one CPU, all green and no red:

```
-l select=2:green=true:red=false:ncpus=1
```

Example 4-2: This job script snippet has a job-wide request for `walltime` and a chunk request for CPUs and memory where the Boolean resource `HasMyApp` is *True*:

```
#PBS -l walltime=1:00:00
```

```
#PBS -l select=ncpus=4:mem=400mb:HasMyApp=true
```

Keep in mind the difference between requesting a vnode-level boolean and a job-wide boolean:

```
qsub -l select=1:green=True
```

requests a vnode with `green` set to *True*. However,

```
qsub -l green=True
```

requests `green` set to *True* on the server and/or queue.

### 4.3.5 Requesting Application Licenses

Application licenses are managed as resources defined by your PBS administrator. PBS doesn't actually check out the licenses; the application being run inside the job's session does that.

#### 4.3.5.1 Requesting Floating Application Licenses

A site-wide floating license is typically configured as a server-level, job-wide resource.

To request a job-wide application license called `AppF`, use:

```
qsub -l AppF=<number of licenses> <other qsub arguments>
```

If only certain hosts can run the application, they will typically have a host-level Boolean resource set to *True*.

The job-wide resource `AppF` is a numerical resource indicating the number of licenses available at the site. The host-level Boolean resource `haveAppF` indicates whether a given host can run the application. To request the application license and the vnodes on which to run the application:

```
qsub -l AppF=<number of licenses> <other qsub arguments>
-l select=haveAppF=True
```

PBS queries the license server to find out how many floating licenses are available at the beginning of each scheduling cycle. PBS doesn't actually check out the licenses, the application being run inside the job's session does that.

#### 4.3.5.2 Requesting Node-locked Application Licenses

Node-locked application licenses are available at the vnode(s) that are licensed for the application. These are host-level (chunk) resources that are requested inside of a `select` statement.

##### 4.3.5.2.i Requesting Per-host Node-locked Application Licenses

Per-host node-locked application licenses are typically configured as a Boolean resource that indicates whether or not the required license is available at that host.

When requesting Boolean-valued per-host node-locked licenses, request one per host. Format:

```
qsub -l select=<Boolean resource name>=true:<rest of chunk specification>
```

Example 4-3: The Boolean resource `runsAppA` specifies whether this vnode has the necessary license. To request a host with a per-host node-locked license for AppA in one chunk:

```
qsub -l select=1:runsAppA=1 <job script>
```

#### 4.3.5.2.ii Requesting Per-use Node-locked Application Licenses

Per-use node-locked application licenses are typically configured as a consumable numeric resource so that the host(s) that run the application have the number of licenses that can be used at one time.

When requesting numerical per-use node-locked licenses, request the required number of licenses for each host:

```
qsub -l select=<consumable resource name>=<required amount>:<rest of chunk specification>
```

Example 4-4: The consumable resource named `AppB` indicates the number of available per-use application licenses on a host. To request a host with a per-use node-locked license for AppB, where you'll run one instance of AppB on two CPUs in one chunk:

```
qsub -l select=1:ncpus=2:AppB=1
```

#### 4.3.5.2.iii Requesting Per-CPU Node-locked Application Licenses

Per-CPU node-locked licenses are typically arranged so that the host has one license for each licensed CPU. The PBS administrator configures a consumable numerical resource indicating the number of available licenses.

You must request one license for each CPU. When requesting numerical per-use node-locked licenses, request the required number of licenses for each host:

```
qsub -l select=<per-CPU resource name>=<required amount>:<rest of chunk specification>
```

Example 4-5: The numerical consumable resource named `AppC` indicates the number of available per-CPU licenses. To request a host with two per-CPU node-locked licenses for AppC, where you'll run a job using two CPUs in one chunk:

```
qsub -l select=1:ncpus=2:AppC=2
```

### 4.3.6 Requesting Scratch Space

Scratch space on a machine is configured as a host-level dynamic resource. Ask your administrator for the name of the scratch space resource.

When requesting scratch space, include the resource in your chunk request:

```
-l select=<scratch resource name>=<amount of scratch needed>:<rest of chunk specification>
```

Example 4-6: Your administrator has named the scratch resource “`dynscratch`”. To request 10MB of scratch space in one chunk:

```
-l select=1:ncpus=N:dynscratch=10MB
```

### 4.3.7 Requesting GPUs

Your PBS job can request GPUs. How you request GPUs depends on whether PBS uses cgroups to manage GPUs; check with your administrator.

### 4.3.7.1 Requesting GPUs Managed via Cgroups

Recommended: On Linux only, PBS can be configured to use cgroups to fence GPUs off, so that when your job requests GPUs it automatically gets exclusive use of its GPUs. You don't have to request exclusivity. When PBS uses cgroups to manage GPUs, you request the number of GPUs you want via the *ngpus* resource:

```
qsub -l select=ngpus=<value>:<rest of chunk specification>
```

When GPUs are managed via cgroups, jobs requesting memory will use that amount both for physical memory and for swap. For example, a job that requests 20GB and uses 16GB but reads a 50GB file can only swap 4GB at a time. So if a job requires 32GB of application memory but also requires 5GB of private file cache to perform adequately, then it needs to request 37GB.

### 4.3.7.2 Requesting GPUs Not Managed via Cgroups

On Windows or Linux, when PBS is not using cgroups to manage GPUs, your administrator can configure PBS to support any of the following:

- (“Basic GPU scheduling”) Job uses non-specific GPUs and exclusive use of a node
- (“Advanced GPU scheduling”) Job uses non-specific GPUs and shared use of a node
- (“Advanced GPU scheduling”) Job uses specific GPUs and either shared or exclusive use of a node

#### 4.3.7.2.i Binding to GPUs

PBS Professional allocates GPUs, but does not bind jobs to any particular GPU; the application itself, or the CUDA library, is responsible for the actual binding.

#### 4.3.7.2.ii Requesting Non-specific GPUs and Exclusive Use of Node

When your site uses “basic GPU scheduling”, if your job needs GPUs, but does not require specific GPUs, and can request exclusive use of GPU nodes, you can request GPUs the same way you request CPUs.

Your administrator can set up a resource to represent the GPUs on a node. We recommend that the GPU resource is called *ngpus*.

When requesting GPUs in this manner, your job should request exclusive use of the node to prevent other jobs being scheduled on its GPUs.

```
qsub -l select=ngpus=<value>:<rest of chunk specification> -lplace=excl
```

Example 4-7: To submit the job named “*my\_gpu\_job*”, requesting one node with two GPUs and one CPU, and exclusive use of the node:

```
qsub -lselect=1:ncpus=1:ngpus=2 -lplace=excl my_gpu_job
```

It is up to the application or CUDA to bind the GPUs to the application processes.

#### 4.3.7.2.iii Requesting Non-specific GPUs and Shared Use of Node

When your site uses “advanced GPU scheduling”, your administrator can configure PBS to allow your job to use non-specific GPUs on a node while sharing GPU nodes. In this case, your administrator puts each GPU in its own vnode.

Your administrator can configure a resource to represent GPUs. We recommend that the GPU resource is called *ngpus*.

Your administrator can configure each GPU vnode so it has a resource containing the device number of the GPU. We recommend that this resource is called *gpu\_id*.

Example 4-8: To submit the job named “*my\_gpu\_job*”, requesting two GPUs and one CPU, and shared use of the node:

```
qsub -lselect=1:ncpus=1:ngpus=2 -lplace=shared my_gpu_job
```

When a job is submitted requesting any GPU, the PBS scheduler looks for a vnode with an available GPU and assigns that vnode to the job. Since there is a one-to-one correspondence between GPUs and vnodes, the job can determine the `gpu_id` of that vnode. Finally, the application can use the appropriate CUDA call to bind the process to the allocated GPU.

#### 4.3.7.2.iv Requesting Specific GPUs

When your site uses “advanced GPU scheduling”, your job can request one or more specific GPUs. This allows you to run applications on the GPUs for which the applications are written.

Your administrator can set up a resource to allow jobs to request specific GPUs. We recommend that the GPU resource is called `gpu_id`.

When you request specific GPUs, specify the GPU that you want for each chunk:

```
qsub -l select=gpu_id=<GPU ID>:<rest of chunk specification>
```

Example 4-9: To request 4 vnodes, each with GPU with ID 0:

```
qsub -lselect=4:ncpus=1:ngpus=1:gpu_id=gpu0 my_gpu_job
```

When a job is submitted requesting specific GPUs, the PBS scheduler assigns the vnode with the resource containing that `gpu_id` to the job. The application can use the appropriate CUDA call to bind the process to the allocated GPU.

#### 4.3.7.3 Viewing GPU Information for Nodes

You can find the number of GPUs available and assigned on execution hosts via the `pbsnodes` command. See [section 4.6, “Viewing Resources”, on page 63](#).

### 4.3.8 Caveats and Restrictions on Requesting Resources

#### 4.3.8.1 Caveats and Restrictions for Specifying Resource Values

- Resource values which contain commas, quotes, plus signs, equal signs, colons, or parentheses must be quoted to PBS. The string must be enclosed in quotes so that the command (e.g. `qsub`, `qalter`) will parse it correctly.
- When specifying resources via the command line, any quoted strings must be escaped or enclosed in another set of quotes. This second set of quotes must be different from the first set, meaning that double quotes must be enclosed in single quotes, and vice versa.
- If a string resource value contains spaces or shell metacharacters, enclose the string in quotes, or otherwise escape the space and metacharacters. Be sure to use the correct quotes for your shell and the behavior you want.

#### 4.3.8.2 Warning About NOT Requesting walltime

If your job does not request a walltime, and there is no default for walltime, your job is treated as if it had requested a very, very long walltime. Translation: the scheduler will have a hard time finding a time slot for your job. Remember, the administrator may schedule dedicated time for the entire PBS complex once a year, for upgrading, etc. In this case, your job will never run. We recommend requesting a reasonable walltime for your job.

#### 4.3.8.3 Caveats for Jobs Requesting Undefined Resources

If you submit a job that requests a job-wide or host-level resource that is undefined, the job is not rejected at submission; instead, it is aborted upon being enqueued in an execution queue, if the resources are still undefined. This preserves backward compatibility.

#### 4.3.8.4 Matching Resource Requests with Unset Resources

When job resource requests are being matched with available resources, a numerical resource that is unset on a host is treated as if it were zero, and an unset string cannot satisfy a request. An unset Boolean resource is treated as if it were set to *False*. An unset resource at the server or queue is treated as if it were infinite.

#### 4.3.8.5 Caveat for Invisible or Unrequestable Resources

Your administrator may define custom resources which restricted, so that they are invisible, or are visible but unrequestable. Custom resources which were created to be invisible or unrequestable cannot be requested or altered. The following is a list of the commands normally used to view or request resources or modify resource requests, and their limitations for restricted resources:

`pbsnodes`

Job submitters cannot view restricted host-level custom resources.

`pbs_rstat`

Job submitters cannot view restricted reservation resources.

`pbs_rsub`

Job submitters cannot request restricted custom resources for reservations.

`qalter`

Job submitters cannot alter a restricted resource.

`qmgr`

Job submitters cannot print or list a restricted resource.

`qselect`

Job submitters cannot specify restricted resources via `-l Resource_List`.

`qsub`

Job submitters cannot request a restricted resource.

`qstat`

Job submitters cannot view a restricted resource.

#### 4.3.8.6 Warning About Requesting Tiny Amounts of Memory

The smallest unit of memory you can request is 1KB. If you request 400 bytes, you get 1KB. If you request 1400 bytes, you get 2KB.

#### 4.3.8.7 Maximum Length of Job Submission Command Line

The maximum length of a command line in PBS is 4095 characters. When you submit a job using the command line, your select and place statements, and the rest of your command line, must fit within 4095 characters.

#### 4.3.8.8 Only One select Statement Per Job

You can include at most one select statement per job submission.

#### 4.3.8.9 The software Resource is Job-wide

The built-in resource "software" is not a vnode-level resource. See [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#).

### 4.3.8.10 Do Not Mix Old and New Syntax

Do not mix old and new syntax when requesting resources. See [section 4.8, “Backward Compatibility”, on page 70](#) for a description of old syntax.

## 4.4 How Resources are Allocated to Jobs

Resources are allocated to your job when the job explicitly requests them, and when PBS applies defaults.

Jobs explicitly request resources either at the vnode level in chunks defined in a selection statement, or in job-wide resource requests. We will cover requesting resources in [section 4.3.3, “Requesting Resources in Chunks”, on page 53](#) and [section 4.3.2, “Requesting Job-wide Resources”, on page 52](#).

The administrator can set default resources at the server and at queues, so that a job that does not request a resource at submission time ends up being allocated the default value for that resource. We will cover default resources in [section 4.4.1, “Applying Default Resources”, on page 59](#).

The administrator can also specify default arguments for `qsub` so that jobs automatically request certain resources. Resource values explicitly requested by your job override any `qsub` defaults. See [“qsub” on page 213 of the PBS Professional Reference Guide](#).

### 4.4.1 Applying Default Resources

PBS applies resource defaults only where the job has not explicitly requested a value for a resource.

Job-wide and per-chunk resources are applied, with the following order of precedence, via the following:

1. Resources that are explicitly requested via `-l <resource>=<value>` and `-l select=<chunk>`
2. Default `qsub` arguments
3. The queue’s `default_chunk.<resource>`
4. The server’s `default_chunk.<resource>`
5. The queue’s `resources_default.<resource>`
6. The server’s `resources_default.<resource>`
7. The queue’s `resources_max.<resource>`
8. The server’s `resources_max.<resource>`

#### 4.4.1.1 Applying Job-wide Default Resources

The explicit job-wide resource request is checked first against default `qsub` arguments, then against queue resource defaults, then against server resource defaults. Any default job-wide resources not already in the job’s resource request are added. PBS applies job-wide default resources defined in the following places, in this order:

- Via `qsub`: The server’s `default_qsub_arguments` attribute can include any requestable job-wide resources.
- Via the queue: Each queue’s `resources_default` attribute defines each queue-level job-wide resource default in `resources_default.<resource>`.
- Via the server: The server’s `resources_default` attribute defines each server-level job-wide resource default in `resources_default.<resource>`.

### 4.4.1.2 Applying Per-chunk Default Resources

For each chunk in the job's selection statement, first `qsub` defaults are applied, then queue chunk defaults are applied, then server chunk defaults are applied. If the chunk request does not include a resource listed in the defaults, the default is added. PBS applies default chunk resources in the following order:

- Via `qsub`: The server's `default_qsub_arguments` attribute can include any requestable chunk resources.
- Via the queue: Each queue's `default_chunk` attribute defines each queue-level chunk resource default in `default_chunk.<resource>`.
- Via the server: The server's `default_chunk` attribute defines each server-level chunk resource default in `default_chunk.<resource>`.

Example 4-10: Applying chunk defaults: if the queue in which the job is enqueued has the following defaults defined:

```
default_chunk.ncpus=1
```

```
default_chunk.mem=2gb
```

A job submitted with this selection statement:

```
select=2:ncpus=4+1:mem=9gb
```

The job has this specification after the `default_chunk` elements are applied:

```
select=2:ncpus=4:mem=2gb+1:ncpus=1:mem=9gb.
```

In this example, `mem=2gb` and `ncpus=1` are inherited from `default_chunk`.

### 4.4.1.3 Caveat for Moving Jobs From One Queue to Another

If the job is moved from the current queue to a new queue, any default resources in the job's resource list that were contributed by the current queue are removed. This includes a select specification and place directive generated by the rules for conversion from the old syntax. If a job's resource is unset (undefined) and there exists a default value at the new queue or server, that default value is applied to the job's resource list. If either select or place is missing from the job's new resource list, it will be automatically generated, using any newly inherited default values.

Given the following set of queue and server default values:

Server

```
resources_default.ncpus=1
```

Queue QA

```
resources_default.ncpus=2
```

```
default_chunk.mem=2gb
```

Queue QB

```
default_chunk.mem=1gb
```

no default for ncpus

The following examples illustrate the equivalent select specification for jobs submitted into queue QA and then moved to (or submitted directly to) queue QB:

```
qsub -l ncpus=1 -lmem=4gb
```

In QA: `select=1:ncpus=1:mem=4gb`

No defaults need be applied

In QB: `select=1:ncpus=1:mem=4gb`

No defaults need be applied

```
qsub -l ncpus=1
```

In QA: `select=1:ncpus=1:mem=2gb`

Picks up 2gb from queue default chunk and 1 ncpus from qsub

In QB: select=1:ncpus=1:mem=1gb

Picks up 1gb from queue default chunk and 1 ncpus from qsub

**qsub -lmem=4gb**

In QA: select=1:ncpus=2:mem=4gb

Picks up 2 ncpus from queue level job-wide resource default and 4gb mem from qsub

In QB: select=1:ncpus=1:mem=4gb

Picks up 1 ncpus from server level job-wide default and 4gb mem from qsub

**qsub -lnodes=4**

In QA: select=4:ncpus=1:mem=2gb

Picks up a queue level default memory chunk of 2gb. (This is not 4:ncpus=2 because in prior versions, "nodes=x" implied 1 CPU per node unless otherwise explicitly stated.)

In QB: select=4:ncpus=1:mem=1gb

(In prior versions, "nodes=x" implied 1 CPU per node unless otherwise explicitly stated, so the ncpus=1 is not inherited from the server default.)

**qsub -l mem=16gb -lnodes=4**

In QA: select=4:ncpus=1:mem=4gb

(This is not 4:ncpus=2 because in prior versions, "nodes=x" implied 1 CPU per node unless otherwise explicitly stated.)

In QB: select=4:ncpus=1:mem=4gb

(In prior versions, "nodes=x" implied 1 CPU per node unless otherwise explicitly stated, so the ncpus=1 is not inherited from the server default.)

## 4.5 Limits on Resource Usage

Jobs are assigned limits on the amount of resources they can use. These limits apply to how much the whole job can use (job-wide limit) and to how much the job can use at each host (host limit). Limits are applied only to resources the job requests or inherits.

Your administrator can configure PBS to enforce limits on mem and ncpus, but the other limits are always enforced.

If you want to make sure that your job does not exceed a given amount of some resource, request that amount of the resource.

### 4.5.1 Enforceable Resource Limits

Limits can be enforced on the following resources:

**Table 4-2: Enforceable Resource Limits**

| Resource Name | Where Specified | Where Enforced | Always Enforced? |
|---------------|-----------------|----------------|------------------|
| cput          | Host            | Host           | Always           |
| mem           | Host            | Host           | Optional         |
| ncpus         | Host            | Host           | Optional         |

Table 4-2: Enforceable Resource Limits

| Resource Name | Where Specified | Where Enforced | Always Enforced? |
|---------------|-----------------|----------------|------------------|
| pcput         | Job-wide        | Per-process    | Always           |
| pmem          | Job-wide        | Per-process    | Always           |
| pvmem         | Job-wide        | Per-process    | Always           |
| vmem          | Host            | Host           | Always           |
| walltime      | Job-wide        | Job-wide       | Always           |

## 4.5.2 Origins of Resource Limits

Limits are derived from both requested resources and applied default resources. Resource limits are derived in the order shown in [section 4.4.1, “Applying Default Resources”, on page 59](#).

## 4.5.3 Job-wide Resource Limits

Job-wide resource limits set a limit for per-job resource usage. Job resource limits are derived from job-wide resources and from totals of per-chunk consumable resources. Limits are derived from explicitly requested resources and default resources.

Job-wide resource limits that are derived from sums of all chunks override those that are derived from job-wide resources.

Example 4-11: Job-wide limits are derived from sums of chunks. With the following chunk request:

```
qsub -lselect=2:ncpus=3:mem=4gb:arch=linux
```

The following job-wide limits are derived:

```
ncpus=6
```

```
mem=8gb
```

## 4.5.4 Per-chunk Resource Limits

Each chunk's per-chunk limits determine how much of any resource can be used at that host. PBS sums the chunk limits at each host, and uses that sum as the limit at that resource. Per-chunk resource usage limits are the amount of per-chunk resources allocated to the job, both from explicit requests and from defaults.

### 4.5.4.1 Effects of Limits

If a running job exceeds its limit for `walltime`, the job is terminated.

If any of the job's processes exceed the limit for `pcput`, `pmem`, or `pvmem`, the job is terminated.

If any of the host limits for `mem`, `ncpus`, `cput`, or `vmem` is exceeded, the job is terminated. These are host-level limits, so if for example your job has two chunks on one host, and the processes on one chunk exceed one of these limits, but the processes on the other are under the chunk limit, the job can continue to run as long as the total used for both chunks is less than the host limit.

## 4.5.5 Examples of Memory Limits

Your administrator may choose to enforce memory limits. If this is the case, the memory used by the entire job cannot exceed the amount in `Resource_List.mem`, and the memory used at any host cannot exceed the sum of the chunks on that host. For the following examples, assume the following:

The queue has these settings:

```
resources_default.mem=200mb
default_chunk.mem=100mb
```

Example 4-12: A job requesting `-l select=2:ncpus=1:mem=345mb` uses 345mb from each of two vnodes and has a job-wide limit of 690mb ( $2 * 345$ ). The job's `Resource_List.mem` shows *690mb*.

Example 4-13: A job requesting `-l select=2:ncpus=2` takes 100mb via `default_chunk` from each vnode and has a job-wide limit of 200mb ( $2 * 100$ mb). The job's `Resource_List.mem` shows *200mb*.

Example 4-14: A job requesting `-l ncpus=2` takes 200mb (inherited from `resources_default` and used to create the select specification) from one vnode and has a job-wide limit of 200mb. The job's `Resource_List.mem` shows *200mb*.

Example 4-15: A job requesting `-lnodes=2` inherits 200mb from `resources_default.mem` which becomes the job-wide limit. The memory is taken from the two vnodes, half (100mb) from each. The generated select specification is `2:ncpus=1:mem=100mb`. The job's `Resource_List.mem` shows *200mb*.

## 4.6 Viewing Resources

You can look at the resources on the server, queue, and vnodes. You can also see what resources are allocated to and used by your job.

### 4.6.1 Viewing Server, Queue, and Vnode Resources

To see server resources:

```
qstat -Bf
```

To see queue resources:

```
qstat -Qf
```

To see vnode resources, use any of the following:

```
qmgr -c "list node <vnode name> <attribute name>"
pbsnodes -av
pbsnodes [<host list>]
```

Look at the following attributes:

`resources_available.<resource name>`

(Server, queue, vnode) Total amount of the resource available at the server, queue, or vnode; does not take into account how much of the resource is in use.

`resources_default.<resource name>`

(Server, queue) Default value for job-wide resource. This amount is allocated to job if job does not request this resource. Queue setting overrides server setting.

`resources_max.<resource name>`

(Server, queue) Maximum amount that a single job can request. Queue setting overrides server setting.

`resources_min.<resource name>`

(Queue) Minimum amount that a single job can request.

`resources_assigned.<resource name>`

(Server, queue, vnode) Total amount of the resource that has been allocated to running and exiting jobs and reservations at the server, queue, or vnode.

## 4.6.2 Viewing Job Resources

To see the resources allocated to or used by your job:

```
qstat -f
```

Look at the following job attributes:

`Resource_List.<resource name>`

The amount of the resource that has been allocated to the job, including defaults.

`resources_used.<resource name>`

The amount of the resource used by the job.

### 4.6.2.1 Resources Shown in Resource\_List Job Attribute

When your job requests a job-wide resource or any of certain built-in host-level resources, the value requested is stored in the job's `Resource_List` attribute, as `Resource_List.<resource name>=<value>`. When you request a built-in host-level resource inside multiple chunks, the value in `Resource_List` is the sum over all of the chunks for that resource. For a list of the resources that can appear in `Resource_List`, see [section 5.9.2, "Resources Requested by Job", on page 245 of the PBS Professional Administrator's Guide](#).

If your administrator has defined default values for any of those resources, and your job has inherited any defaults, those defaults control the value shown in the `Resource_List` attribute.

## 4.7 Specifying Job Placement

You can specify how your job should be placed on vnodes. You can choose to place each chunk on a different host, or a different vnode, or your job can use chunks that are all on one host. You can specify that all of the job's chunks should share a value for some resource.

Your job can request exclusive use of each vnode, or shared use with other jobs. Your job can request exclusive use of its hosts.

We will cover the basics of specifying job placement in the following sections. For details on placing chunks for an MPI job, see ["Submitting Multiprocessor Jobs"](#).

### 4.7.1 Using the place Statement

You use the *place* statement to specify how the job's chunks are placed.

The *place* statement can contain the following elements in any order:

```
-l place=[<arrangement>][: <sharing>][: <grouping>]
```

where

*arrangement*

Whether this chunk is willing to share this vnode or host with other chunks from the same job. One of *free* | *pack* | *scatter* | *vscatter*

*sharing*

Whether this this chunk is willing to share this vnode or host with other jobs. One of *excl* | *shared* | *exclhost*

*grouping*

Whether the chunks from this job should be placed on vnodes that all have the same value for a resource. Can have only one instance of *group=<resource name>*

and where

**Table 4-3: Placement Modifiers**

| Modifier                      | Meaning                                                                                                                                                                                            |
|-------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>free</i>                   | Place job on any vnode(s)                                                                                                                                                                          |
| <i>pack</i>                   | All chunks will be taken from one host                                                                                                                                                             |
| <i>scatter</i>                | Only one chunk is taken from any host                                                                                                                                                              |
| <i>vscatter</i>               | Only one chunk is taken from any vnode.<br>Each chunk must fit on a vnode.                                                                                                                         |
| <i>excl</i>                   | Only this job uses the vnodes chosen                                                                                                                                                               |
| <i>exclhost</i>               | The entire host is allocated to this job                                                                                                                                                           |
| <i>shared</i>                 | This job can share the vnodes chosen                                                                                                                                                               |
| <i>group=&lt;resource&gt;</i> | Chunks will be placed on vnodes according to a resource shared by those vnodes. This resource must be a string or string array. All vnodes in the group must have a common value for the resource. |

The place statement may be not be used without the select statement.

The place statement may not begin with a colon.

### 4.7.1.1 Specifying Arrangement of Chunks

To place your job's chunks wherever they fit:

```
-l place=free
```

To place all of the job's chunks on a single host:

```
-l place=pack
```

To place each chunk on its own host:

```
-l place=scatter
```

To place each chunk on its own vnode:

```
-l place=vscatter
```

#### 4.7.1.1.i Caveats and Restrictions for Arrangement

- For all arrangements except *vscluster*, chunks cannot be split across hosts, but they can be split across vnodes on the same host. If a job does not request *vscluster* for its arrangement, any chunk can be broken across vnodes. This means that one chunk could be taken from more than one vnode.
- If the job requests *vscluster* for its arrangement, no chunk can be larger than a vnode, and no chunk can be split across vnodes. This behavior is different from other values for arrangement, where chunks can be split across vnodes.

#### 4.7.1.2 Specifying Shared or Exclusive Use of Vnodes

Each vnode can be allocated exclusively to one job, or its resources can be shared among jobs. Hosts can also be allocated exclusively to one job, or shared among jobs.

How vnodes are allocated to jobs is determined by a combination of the vnode's **sharing** attribute and the job's resource request. The possible values for the vnode **sharing** attribute, and how they interact with a job's placement request, are described in ["sharing" on page 324 of the PBS Professional Reference Guide](#). The following table expands on this:

**Table 4-4: How Vnode sharing Attribute Affects Vnode Allocation**

| Value of Vnode sharing Attribute | Effect on Allocation                                                                                                           |
|----------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| not set                          | The job's arrangement request determines how vnodes are allocated to the job. If there is no specification, vnodes are shared. |
| <i>default_share</i>             | Vnodes are shared unless the job explicitly requests exclusive use of the vnodes.                                              |
| <i>default_excl</i>              | Vnodes are allocated exclusively to the job unless the job explicitly requests shared allocation.                              |
| <i>default_exclhost</i>          | All vnodes from this host are allocated exclusively to the job, unless the job explicitly requests shared allocation.          |
| <i>ignore_excl</i>               | Vnodes are shared, regardless of the job's request.                                                                            |
| <i>force_excl</i>                | Vnodes are allocated exclusively to the job, regardless of the job's request.                                                  |
| <i>force_exclhost</i>            | All vnodes from this host are allocated exclusively to the job, regardless of the job's request.                               |

If a vnode is allocated exclusively to a job, all of its resources are assigned to the job. The state of the vnode becomes *job-exclusive*. No other job can use the vnode.

If a host is to be allocated exclusively to one job, all of the host must be used: if any vnode from a host has its **sharing** attribute set to either *default\_exclhost* or *force\_exclhost*, all vnodes on that host must have the same value for the **sharing** attribute.

If your job requests exclusive placement, and it is in a reservation, the reservation must also request exclusive placement via `-l place=excl`.

To see the value for a vnode's **sharing** attribute, you can do either of the following:

- Use `qmgr`:  
`Qmgr: list node <vnode name> sharing`
- Use `pbsnodes`:  
`pbsnodes -av`

### 4.7.1.3 Grouping on a Resource

You can specify that all of the chunks for your job should run on vnodes that have the same value for a selected resource.

To group your job's chunks this way, use the following format:

`-l place=group=<resource name>`

where *resource name* is a string or string array.

The value of the resource can be one or more strings at each vnode, but there must be one string that is the same for each vnode. For example, if the resource is *router*, the value can be "*r1i0,r1*" at one vnode, and "*r1i1,r1*" at another vnode, and these vnodes can be grouped because they share the string "*r1*".

Using the method of grouping on a resource, you cannot specify what the value of the resource should be, only that all vnodes have the same value. If you need the resource to have a specific value, specify that value in the description of the chunks.

#### 4.7.1.3.i Grouping vs. Placement Sets

Your administrator may define placement sets for your site. A placement set is a group of vnodes that share a value for a resource. By default, placement sets attempt to group vnodes that are "close to" each other. If your job doesn't request a specific placement, and placement sets are defined, your job may automatically run in a placement set. See ["Placement Sets" on page 168 in the PBS Professional Administrator's Guide](#).

If your job requests grouping by a resource, using `place=group=resource`, the chunks are placed as requested and placement sets are ignored.

If your job requests grouping but no group contains the required number of vnodes, grouping is ignored.

## 4.7.2 How the Job Gets its Place Statement

If the administrator has defined default values for arrangement, sharing, and grouping, each job inherits these unless it explicitly requests at least one. That means that if your job requests arrangement, but not sharing or grouping, it will not inherit values for sharing or grouping. For example, the administrator sets a default of `place=pack:exclhost:group=host`. Job A requests `place=free`, but doesn't specify sharing or grouping, so Job A does not inherit sharing or grouping. Job B does not request any placement, so it inherits all three.

The place statement can be specified, in order of precedence, via:

1. Explicit placement request in `qalter`
2. Explicit placement request in `qsub`
3. Explicit placement request in PBS job script directives
4. Default `qsub` place statement
5. Queue default placement rules
6. Server default placement rules
7. Built-in default conversion and placement rules

---

### 4.7.3 Caveats and Restrictions for Specifying Placement

- The place specification cannot be used without the select specification. In other words, you can only specify placement when you have specified chunks.
- A select specification cannot be used with a nodes specification.
- A select specification cannot be used with old-style resource requests such as -lncpus, -lmem, -lvmem, -larch, -lhost.
- When using *place=group=<resource>*, the resource must be a string or string array.
- Do not mix old and new syntax when requesting placement. See [section 4.8, “Backward Compatibility”, on page 70](#) for a description of old syntax.
- If your job requests exclusive placement, and it is in a reservation, the reservation must also request exclusive placement via -l place=excl.

### 4.7.4 Examples of Specifying Placement

Unless otherwise specified, the vnodes allocated to the job will be allocated as shared or exclusive based on the setting of the vnode’s sharing attribute. Each of the following shows how you would use -l select= and -l place=.

1. A job that will fit in a single host but not in any of the vnodes, packed into the fewest vnodes:

```
-l select=1:ncpus=10:mem=20gb
-l place=pack
```

In earlier versions, this would have been:

```
-lncpus=10,mem=20gb
```

2. Request four chunks, each with 1 CPU and 4GB of memory taken from anywhere.

```
-l select=4:ncpus=1:mem=4GB
-l place=free
```

3. Allocate 4 chunks, each with 1 CPU and 2GB of memory from between

one and four vnodes which have an arch of “linux”.

```
-l select=4:ncpus=1:mem=2GB:arch=linux -l place=free
```

4. Allocate four chunks on 1 to 4 vnodes where each vnode must have 1 CPU, 3GB of memory and 1 node-locked dyna license available for each chunk.

```
-l select=4:dyna=1:ncpus=1:mem=3GB -l place=free
```

5. Allocate four chunks on 1 to 4 vnodes, and 4 floating dyna licenses. This assumes “dyna” is specified as a server dynamic resource.

```
-l dyna=4 -l select=4:ncpus=1:mem=3GB -l place=free
```

6. This selects exactly 4 vnodes where the arch is linux, and each vnode will be on a separate host. Each vnode will have 1 CPU and 2GB of memory allocated to the job.

```
-lselect=4:mem=2GB:ncpus=1:arch=linux -lplace=scatter
```

7. This will allocate 3 chunks, each with 1 CPU and 10GB of memory. This will also reserve 100mb of scratch space if scratch is to be accounted. Scratch is assumed to be on a file system common to all hosts. The value of “place” depends on the default which is “place=free”.

```
-l scratch=100mb -l select=3:ncpus=1:mem=10GB
```

8. This will allocate 2 CPUs and 50GB of memory on a host named zooland. The value of “place” depends on the default which defaults to “place=free”:

```
-l select=1:ncpus=2:mem=50gb:host=zooland
```

9. This will allocate 1 CPU and 6GB of memory and one host-locked swlicense from each of two hosts:

```
-l select=2:ncpus=1:mem=6gb:swlicense=1
-lplace=scatter
```

10. Request free placement of 10 CPUs across hosts:

```
-l select=10:ncpus=1
-l place=free
```

11. Here is an odd-sized job that will fit on a single HPE system, but not on any one node-board. We request an odd number of CPUs that are not shared, so they must be “rounded up”:

```
-l select=1:ncpus=3:mem=6gb
-l place=pack:excl
```

12. Here is an odd-sized job that will fit on a single HPE system, but not on any one node-board. We are asking for small number of CPUs but a large amount of memory:

```
-l select=1:ncpus=1:mem=25gb
-l place=pack:excl
```

13. Here is a job that may be run across multiple HPE systems, packed into the fewest vnodes:

```
-l select=2:ncpus=10:mem=12gb
-l place=free
```

14. Submit a job that must be run across multiple HPE systems, packed into the fewest vnodes:

```
-l select=2:ncpus=10:mem=12gb
-l place=scatter
```

15. Request free placement across nodeboards within a single host:

```
-l select=1:ncpus=10:mem=10gb
```

- 
- l place=group=host
  - 16. Request free placement across vnodes on multiple HPE systems:
    - l select=10:ncpus=1:mem=1gb
    - l place=free
  - 17. Here is a small job that uses a shared cpuset:
    - l select=1:ncpus=1:mem=512kb
    - l place=pack:shared
  - 18. Request a special resource available on a limited set of nodeboards, such as a graphics card:
    - l select= 1:ncpus=2:mem=2gb:graphics=True + 1:ncpus=20:mem=20gb:graphics=False
    - l place=pack:excl
  - 19. Align SMP jobs on c-brick boundaries:
    - l select=1:ncpus=4:mem=6gb
    - l place=pack:group=cbrick
  - 20. Align a large job within one router, if it fits within a router:
    - l select=1:ncpus=100:mem=200gb
    - l place=pack:group=router
  - 21. Fit large jobs that do not fit within a single router into as few available routers as possible. Here, RES is the resource used for node grouping:
    - l select=1:ncpus=300:mem=300gb
    - l place=pack:group=<RES>
  - 22. To submit an MPI job, specify one chunk per MPI task. For a 10-way MPI job with 2gb of memory per MPI task:
    - l select=10:ncpus=1:mem=2gb
  - 23. To submit a non-MPI job (including a 1-CPU job or an OpenMP or shared memory) job, use a single chunk. For a 2-CPU job requiring 10gb of memory:
    - l select=1:ncpus=2:mem=10gb

## 4.8 Backward Compatibility

### 4.8.1 Old-style Resource Specifications

Old versions of PBS allowed job submitters to ask for resources outside of a select statement, using “-lresource=value”, where those resources must now be requested in chunks, inside a select statement. This old style of resource request was called a “resource specification”. Resource specification syntax is **deprecated**.

For backward compatibility, any resource specification is converted to select and place statements, and any defaults are applied.

### 4.8.2 Old-style Node Specifications

In early versions of PBS, job submitters used “-l nodes=...” in what was called a “node specification” to specify where the job should run. The syntax for a “node specification” is **deprecated**.

For backward compatibility, a legal node specification or resource specification is converted into select and place directives; we show how in following sections.

## 4.8.3 Conversion of Old Style to New

### 4.8.3.1 Conversion of Resource Specifications

If your job has an old-style resource specification, PBS creates a select specification requesting 1 chunk containing the resources specified by the job and server and/or queue default resources. Resource specification format:

```
-l <resource>=<value>[:<resource>=<value> ...]
```

The resource specification is converted to:

```
-lselect=1[:<resource>=<value> ...]
```

```
-lplace=pack
```

with one instance of *resource=value* for each of the following vnode-level resources in the resource request:

built-in resources: ncpus | mem | vmem | arch | host

site-defined vnode-level resources

For example, a job submitted with

```
qsub -l ncpus=4:mem=123mb:arch=linux
```

gets the following select statement:

```
select=1:ncpus=4:mem=123mb:arch=linux
```

### 4.8.3.2 Conversion of Node Specifications

If your job requests a node specification, PBS creates a select and place specification, according to the following rules.

Old node specification format:

```
-lnodes=[N:<spec list> | <spec list>]
```

```
[[+N:<spec list> | +<spec list>] ...]
```

```
[#<suffix> ...][-lncpus=Z]
```

where:

*spec list* has syntax: <spec>[:<spec> ...]

*spec* is any of: hostname | property | ncpus=X | cpp=X | ppn=P

*suffix* is any of: property | excl | shared

N and P are positive integers

X and Z are non-negative integers

The node specification is converted into select and place statements as follows:

Each *spec list* is converted into one chunk, so that N:<spec list> is converted into N chunks.

If *spec* is hostname :

The chunk will include *host=hostname*

If *spec* matches any vnode's *resources\_available.<hostname>* value:

The chunk will include *host=hostname*

If *spec* is property :

The chunk will include `<property>=true`

Property must be a site-defined vnode-level boolean resource.

If *spec* is `ncpus=X` or `cpp=X` :

The chunk will include `ncpus=X`

If no *spec* is `ncpus=X` and no *spec* is `cpp=X` :

The chunk will include `ncpus=P`

If *spec* is `ppn=P` :

The chunk will include `mpiprocs=P`

If the *nodespec* is

`-lnodes=N:ppn=P`

It is converted to

`-lselect=N:ncpus=P:mpiprocs=P`

Example:

`-lnodes=4:ppn=2`

is converted into

`-lselect=4:ncpus=2:mpiprocs=2`

If `-lncpus=Z` is specified and no *spec* contains `ncpus=X` and no *spec* is `cpp=X` :

Every chunk will include `ncpus=W`, where *W* is *Z* divided by the total number of chunks. (Note: *W* must be an integer; *Z* must be evenly divisible by the number of chunks.)

If *property* is a suffix :

All chunks will include `property=true`

If *excl* is a suffix :

The placement directive will be `-lplace=scatter:excl`

If *shared* is a suffix :

The placement directive will be `-lplace=scatter:shared`

If neither *excl* nor *shared* is a suffix :

The placement directive will be `-lplace=scatter`

Example:

`-lnodes=3:green:ncpus=2:ppn=2+2:red`

is converted to:

`-l select=3:green=true:ncpus=4:mpiprocs=2+ 2:red=true:ncpus=1`

`-l place=scatter`

### 4.8.3.3 Examples of Converting Old Syntax to New

1. Request CPUs and memory on a single host using old syntax:

`-l ncpus=5,mem=10gb`

is converted into the equivalent:

```
-l select=1:ncpus=5:mem=10gb
-l place=pack
```

2. Request CPUs and memory on a named host along with custom resources including a floating license using old syntax:

```
-l ncpus=1,mem=5mb,host=sunny,opti=1,arch=arch1
```

is converted to the equivalent:

```
-l select=1:ncpus=1:mem=5gb:host=sunny:arch=arch1
-l place=pack
-l opti=1
```

3. Request one host with a certain property using old syntax:

```
-lnodes=1:property
```

is converted to the equivalent:

```
-l select=1:ncpus=1:property=True
-l place=scatter
```

4. Request 2 CPUs on each of four hosts with a given property using old syntax:

```
-lnodes=4:property:ncpus=2
```

is converted to the equivalent:

```
-l select=4: ncpus=2:property=True -l place=scatter
```

5. Request 1 CPU on each of 14 hosts asking for certain software, licenses and a job limit amount of memory using old syntax:

```
-lnodes=14:mpi-fluent:ncpus=1 -lfluent=1,fluent-all=1, fluent-par=13
-l mem=280mb
```

is converted to the equivalent:

```
-l select=14:ncpus=1:mem=20mb:mpi_fluent=True
-l place=scatter
-l fluent=1,fluent-all=1,fluent-par=13
```

6. Requesting licenses using old syntax:

```
-lnodes=3:dyna-mpi-Linux:ncpus=2 -ldyna=6,mem=100mb, software=dyna
```

is converted to the equivalent:

```
-l select=3:ncpus=2:mem=33mb: dyna-mpi-Linux=True
-l place=scatter
-l software=dyna
-l dyna=6
```

7. Requesting licenses using old syntax:

```
-l ncpus=2,app_lic=6,mem=200mb -l software=app
```

is converted to the equivalent:

```
-l select=1:ncpus=2:mem=200mb
-l place=pack
-l software=app
-l app_lic=6
```

8. Additional example using old syntax:

```
-lnodes=1:fserver+15:noserver
```

is converted to the equivalent:

```
-l select=1:ncpus=1:fserver=True + 15:ncpus=1:noserver=True
-l place=scatter
```

but could also be more easily specified with something like:

```
-l select=1:ncpus=1:fserver=True + 15:ncpus=1:fserver=False
-l place=scatter
```

9. Allocate 4 vnodes, each with 6 CPUs with 3 MPI processes per vnode, with each vnode on a separate host. The memory allocated would be one-fourth of the memory specified by the queue or server default if one existed. This results in a different placement of the job from version 5.4:

```
-lnodes=4:ppn=3:ncpus=2
```

is converted to:

```
-l select=4:ncpus=6:mpiprocs=3 -l place=scatter
```

10. Allocate 4 vnodes, from 4 separate hosts, with the property blue. The amount of memory allocated from each vnode is 2560MB (= 10GB / 4) rather than 10GB from each vnode.

```
-lnodes=4:blue:ncpus=2 -l mem=10GB
```

is converted to:

```
-l select=4:blue=True:ncpus=2:mem=2560mb -lplace=scatter
```

## 4.8.4 Caveats for Using Old Syntax

### 4.8.4.1 Changes in Behavior

Most jobs submitted with "-lnodes" will continue to work as expected. These jobs will be automatically converted to the new syntax. However, job tasks may execute in an unexpected order, because vnodes may be assigned in a different order. Jobs submitted with old syntax that ran successfully on versions of PBS Professional prior to 8.0 can fail because a limit that was per-chunk is now job-wide.

Example 4-16: A job submitted using `-lnodes=X -lmem=M` that fails because the mem limit is now job-wide. If the following conditions are true:

- PBS Professional 9.0 or later using standard MPICH
- The job is submitted with `qsub -lnodes=5 -lmem=10GB`
- The master process of this job tries to use more than 2GB

The job is killed, where in  $\leq 7.0$  the master process could use 10GB before being killed. 10GB is now a job-wide limit, divided up into a 2GB limit per chunk.

---

### 4.8.4.2 Do Not Mix Old and New Styles

Do not mix old style resource or node specifications (“-l<resource>=<value>” or “-lnodes”) with select and place statements (“-lselect=” or “-lplace=”). Do not use both in the command line. Do not use both in the job script. Do not use one in a job script and the other on the command line. This will result in an error.

### 4.8.4.3 Resource Request Conversion Dependent on Where Resources are Defined

A job’s resource request is converted from old-style to new according to various rules, one of which is that the conversion is dependent upon where resources are defined. For example: The boolean resource “Red” is defined on the server, and the boolean resource “Blue” is defined at the host level. A job requests “qsub -l Blue=true”. This looks like an old-style resource request, and PBS checks to see where Blue is defined. Since Blue is defined at the host level, the request is converted into “-l select=1:Blue=true”. However, if a job requests “qsub -l Red=true”, while this looks like an old-style resource request, PBS does not convert it to a chunk request because Red is defined at the server.

### 4.8.4.4 Properties are Deprecated

The syntax for requesting properties is **deprecated**. Your administrator has replaced properties with Booleans.

### 4.8.4.5 Replace cpp with ncpus

Specifying “cpp” is part of the old syntax, and should be replaced with “ncpus”.

### 4.8.4.6 Environment Variables Set During Conversion

1. When a node specification is converted into a select statement, the job has the environment variables NCPUS and OMP\_NUM\_THREADS set to the old value of ncpus in the first piece of the old node specification. This may produce incompatibilities with prior versions when a complex node specification using different values of ncpus and ppn in different pieces is converted.

# Multiprocessor Jobs

## 5.1 Submitting Multiprocessor Jobs

Before you read this chapter, please read [Chapter 4, "Allocating Resources & Placing Jobs", on page 49](#).

### 5.1.1 Assigning the Chunks You Want

PBS assigns chunks to job processes in the order in which the chunks appear in the select statement. PBS takes the first chunk from the primary execution host; this is where the top task of the job runs.

Example 5-1: You want three chunks, where the first has two CPUs and 20 GB of memory, the second has four CPUs and 100 GB of memory, and the third has one CPU and five GB of memory:

```
-lselect=1:ncpus=2:mem=20gb+ncpus=4:mem=100gb+mem=5gb
```

#### 5.1.1.1 Specifying Primary Execution Host

The job's primary execution host is the host that supplies the vnode to satisfy the first chunk requested by the job.

#### 5.1.1.2 Request Most Specific Chunks First

Chunk requests are interpreted from left to right. The more specific the chunk, the earlier it should be in the order. For example, if you require a specific host for chunk A, but chunk B is not host-specific, request Chunk A first.

### 5.1.2 The Job Node File

For each job, PBS creates a job-specific "host file" or "node file", which is a text file containing the name(s) of the host(s) containing the vnode(s) allocated to that job. The file is created by the MoM on the primary execution host, and is available only on that host.

#### 5.1.2.1 Node File Format and Contents

The node file contains a list of host names, one per line. The name of the host is the value in `resources_available.host` of the allocated vnode(s). The order in which hosts appear in the PBS node file is the order in which chunks are specified in the selection directive.

The node file contains one line per MPI process with the name of the host on which that process should execute. The number of MPI processes for a job, and the contents of the node file, are controlled by the value of the resource `mpiprocs`. `mpiprocs` is the number of MPI processes per chunk, and defaults to `1` where the chunk contains CPUs, `0` otherwise.

For each chunk requesting `mpiprocs=M`, the name of the host from which that chunk is allocated is written in the node file *M* times. Therefore the number of lines in the node file is the sum of requested `mpiprocs` for all chunks requested by the job.

Example 5-2: Two MPI processes run on HostA and one MPI process runs on HostB. The node file looks like this:

```
HostA
HostA
HostB
```

### 5.1.2.2 Name and Location of Node File

The file is created by the MoM on the primary execution host, in `PBS_HOME/aux/JOB_ID`, where *JOB\_ID* is the job identifier for that job.

The full path and name for the node file is set in the job's environment, in the environment variable `PBS_NODEFILE`.

### 5.1.2.3 Node File for Old-style Requests

For jobs which request resources using the old `-lnodes=nodespec` format, the host for each vnode allocated to the job is listed *N* times, where *N* is the number of MPI ranks on the vnode. The number of MPI ranks is specified via the `ppn` resource.

Example 5-3: Request four vnodes, each with two MPI processes, where each process has three threads, and each thread has a CPU:

```
qsub -lnodes=4:ncpus=3:ppn=2
```

This results in each of the four hosts being written twice, in the order in which the vnodes are assigned to the job.

### 5.1.2.4 Using and Modifying the Node File

You can use `$PBS_NODEFILE` in your job script.

You can modify the node file. You can remove entries or sort the entries.

### 5.1.2.5 Node File Caveats

Do not add entries for new hosts; PBS may terminate processes on those hosts because PBS does not expect the processes to be running there. Adding entries on the same host may cause the job to be terminated because it is using more CPUs than it requested.

### 5.1.2.6 Viewing Execution Hosts

You can see which host is the primary execution host: the primary execution host is the first host listed in the job's node file.

## 5.1.3 Specifying Number of MPI Processes Per Chunk

How you request chunks matters. First, the number of MPI processes per chunk defaults to *1* for chunks with CPUs, and *0* for chunks without CPUs, unless you specify this value using the `mpiprocs` resource. Second, you can specify whether MPI processes share CPUs. For example, requesting one chunk with four CPUs and four MPI processes is not the same as requesting four chunks each with one CPU and one MPI process. In the first case, all four MPI processes are sharing all four CPUs. In the second case, each process gets its own CPU.

You request the number of MPI processes you want for each chunk using the `mpiprocs` resource. For example, to request two MPI processes for each of four chunks, where each chunk has two CPUs:

```
-lselect=4:ncpus=2:mpiprocs=2
```

If you don't explicitly request a value for the `mpiprocs` resource, it defaults to `1` for each chunk requesting CPUs, and `0` for chunks not requesting CPUs.

Example 5-4: To request one chunk with two MPI processes and one chunk with one MPI process, where both chunks have two CPUs:

```
-lselect=ncpus=2:mpiprocs=2+ncpus=2
```

Example 5-5: A request for three vnodes, each with one MPI process:

```
qsub -l select=3:ncpus=2
```

This results in the following node file:

```
<hostname for 1st vnode>
```

```
<hostname for 2nd vnode>
```

```
<hostname for 3rd vnode>
```

Example 5-6: If you want to run two MPI processes on each of three hosts and have the MPI processes share a single processor on each host, request the following:

```
-lselect=3:ncpus=1:mpiprocs=2
```

The node file then contains the following list:

```
hostname for VnodeA
```

```
hostname for VnodeA
```

```
hostname for VnodeB
```

```
hostname for VnodeB
```

```
hostname for VnodeC
```

```
hostname for VnodeC
```

Example 5-7: If you want three chunks, each with two CPUs and running two MPI processes, use:

```
-l select=3:ncpus=2:mpiprocs=2...
```

The node file then contains the following list:

```
hostname for VnodeA
```

```
hostname for VnodeA
```

```
hostname for VnodeB
```

```
hostname for VnodeB
```

```
hostname for VnodeC
```

```
hostname for VnodeC
```

Notice that the node file is the same as the previous example, even though the number of CPUs used is different.

Example 5-8: If you want four MPI processes, where each process has its own CPU:

```
-lselect=4:ncpus=1
```

See [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#) for a definitions of the `mpiprocs` resource.

### 5.1.3.1 Chunks With No MPI Processes

If you request a chunk that has no MPI processes, PBS may take that chunk from a vnode which has already supplied another chunk. You request a chunk that has no MPI processes using either of the following:

```
-lselect=1:ncpus=0
-lselect=1:ncpus=2:mpiprocs=0
```

## 5.1.4 Caveats and Advice for Multiprocessor Jobs

### 5.1.4.1 Requesting Uniform Processors

Some MPI jobs require the work on all vnodes to be at the same stage before moving to the next stage. For these applications, the work can proceed only at the pace of the slowest vnode, because faster vnodes must wait while it catches up. In this case, you may find it useful to ensure that the job's vnodes are homogeneous.

If there is a resource that identifies the architecture, type, or speed of the vnodes, you can use it to ensure that all chunks are taken from vnodes with the same value. You can either request a specific value for this resource for all chunks, or you can group vnodes according to the value of the resource. See [section 4.7.1.3, “Grouping on a Resource”, on page 67](#).

Example 5-9: The resource that identifies the speed is named *speed*, and your job requests 16 chunks, each with two CPUs, two MPI processes, all with *speed* equal to *fast*:

```
-lselect=16:ncpus=2:mpiprocs=2:speed=fast
```

Example 5-10: Request 16 chunks where each chunk has two CPUs, using grouping to ensure that all chunks share the same speed. The resource that identifies the speed is named *speed*:

```
-lselect=16:ncpus=2:mpiprocs=2:place=group=speed
```

### 5.1.4.2 Requesting Storage on NFS Server

One of the vnodes in your complex may act as an NFS server to the rest of the vnodes, so that all vnodes have access to the storage on the NFS server.

Example 5-11: The *scratch* resource is shared among all the vnodes in the complex, and is requested from a central location, called the “*nfs\_server*” vnode. To request two vnodes, each with two CPUs to do calculations, and one vnode with 10gb of memory and no MPI processes:

```
-l select=2:ncpus=2+1:host=nfs_server:scratch=10gb:ncpus=0
```

With this request, your job has one MPI process on each chunk containing CPUs, and no MPI processes on the memory-only chunk. The job shows up as having a chunk on the “*nfs\_server*” host.

## 5.1.5 File Staging for Multiprocessor Jobs

PBS stages files to and from the primary execution host only.

### 5.1.6 Prologue and Epilogue

The prologue is run as root on the primary host, with the current working directory set to `PBS_HOME/mom_priv`, and with `PBS_JOBDIR` and `TMPDIR` set in its environment.

PBS runs the epilogue as root on the primary host. The epilogue is executed with its current working directory set to the job's staging and execution directory, and with `PBS_JOBDIR` and `TMPDIR` set in its environment.

## 5.1.7 MPI Environment Variables

### NCPUS

PBS sets the NCPUS environment variable in the job's environment on the primary execution host. PBS sets NCPUS to the value of `ncpus` requested for the first chunk.

### OMP\_NUM\_THREADS

PBS sets the OMP\_NUM\_THREADS environment variable in the job's environment on the primary execution host. PBS sets this variable to the value of `ompthreads` requested for the first chunk, which defaults to the value of `ncpus` requested for the first chunk.

## 5.1.8 Examples of Multiprocessor Jobs

Example 5-12: For a 10-way MPI job with 2gb of memory per MPI task:

```
qsub -l select=10:ncpus=1:mem=2gb
```

Example 5-13: If you have a cluster of small systems with for example two CPUs each, and you wish to submit an MPI job that will run on four separate hosts:

```
qsub -l select=4:ncpus=1 -l place=scatter
```

In this example, the node file contains one entry for each of the hosts allocated to the job, which is four entries.

The variables NCPUS and OMP\_NUM\_THREADS are set to one.

Example 5-14: If you do not care where the four MPI processes are run:

```
qsub -l select=4:ncpus=1 -l place=free
```

Here, the job runs on two, three, or four hosts depending on what is available.

For this example, the node file contains four entries. These are either four separate hosts, or three hosts, one of which is repeated once, or two hosts, etc.

NCPUS and OMP\_NUM\_THREADS are set to 1, the number of CPUs allocated from the first chunk.

## 5.1.9 Submitting SMP Jobs

To submit an SMP job, simply request a single chunk containing all of the required CPUs and memory, and if necessary, specify the hostname. For example:

```
qsub -l select=ncpus=8:mem=20gb:host=host1
```

When the job is run, the node file will contain one entry, the name of the selected execution host.

The job will have two environment variables, NCPUS and OMP\_NUM\_THREADS, set to the number of CPUs allocated.

## 5.2 Using MPI with PBS

### 5.2.1 Using an Integrated MPI

Many MPIs are integrated with PBS. PBS provides tools to integrate most of them; a few MPIs supply the integration. When a job is run under an integrated MPI, PBS can track resource usage, signal job processes, and perform accounting for all processes of the job.

When a job is run under an MPI that is not integrated with PBS, PBS is limited to managing the job only on the primary vnode, so resource tracking, job signaling, and accounting happen only for the processes on the primary vnode.

The instructions that follow are for integrated MPIs. Check with your administrator to find out which MPIs are integrated at your site. If an MPI is not integrated with PBS, you use it as you would outside of PBS.

Some of the integrated MPIs have slightly different command lines. See the instructions for each MPI.

The following table lists the supported MPIs and gives links to instructions for using each MPI:

**Table 5-1: List of Supported MPIs**

| MPI Name                       | Versions                            | Instructions for Use                                                                           |
|--------------------------------|-------------------------------------|------------------------------------------------------------------------------------------------|
| HP MPI                         | 1.08.03<br>2.0.0                    | See <a href="#">section 5.2.4, “HP MPI with PBS”, on page 84</a>                               |
| Intel MPI                      | 2.0.022<br>3<br>4                   | See <a href="#">section 5.2.7, “Intel MPI 2.0.022, 3, and 4 with PBS”, on page 85</a>          |
| Intel MPI                      | 4.0.3 on Linux                      | See <a href="#">section 5.2.5, “Intel MPI 4.0.3 On Linux with PBS”, on page 85</a>             |
| Intel MPI                      | 4.0.3 on Windows                    | See <a href="#">section 5.2.6, “Intel MPI 4.0.3 On Windows with PBS”, on page 85</a>           |
| LAM MPI                        | 6.5.9                               | <b>Deprecated.</b> See <a href="#">section 5.2.8.2, “Using LAM 6.5.9 with PBS”, on page 89</a> |
| LAM MPI                        | 7.0.6<br>7.1.1                      | <b>Deprecated.</b> See <a href="#">section 5.2.8.1, “Using LAM 7.x with PBS”, on page 88</a>   |
| MPICH-P4<br><b>Deprecated.</b> | 1.2.5<br>1.2.6<br>1.2.7             | See <a href="#">section 5.2.9, “MPICH-P4 with PBS”, on page 89</a>                             |
| MPICH-GM<br><b>Deprecated.</b> |                                     | See <a href="#">section 5.2.10, “MPICH-GM with PBS”, on page 90</a>                            |
| MPICH-MX<br><b>Deprecated.</b> |                                     | See <a href="#">section 5.2.11, “MPICH-MX with PBS”, on page 93</a>                            |
| MPICH2<br><b>Deprecated.</b>   | 1.0.3<br>1.0.5<br>1.0.7<br>On Linux | See <a href="#">section 5.2.12, “MPICH2 with PBS on Linux”, on page 95</a>                     |
| MPICH2                         | 1.4.1p1 on Windows                  | See <a href="#">section 5.2.13, “MPICH2 1.4.1p1 On Windows with PBS”, on page 98</a>           |
| MVAPICH<br><b>Deprecated.</b>  | 1.2                                 | See <a href="#">section 5.2.14, “MVAPICH with PBS”, on page 98</a>                             |
| MVAPICH2                       | 1.8                                 | See <a href="#">section 5.2.15, “MVAPICH2 with PBS”, on page 99</a>                            |
| Open MPI                       | 1.4.x                               | See <a href="#">section 5.2.16, “Open MPI with PBS”, on page 101</a>                           |
| Platform MPI                   | 8.0                                 | See <a href="#">section 5.2.17, “Platform MPI with PBS”, on page 101</a>                       |
| HPE MPI                        | Any                                 | See <a href="#">section 5.2.18, “HPE MPI with PBS”, on page 102</a>                            |

### 5.2.1.1 Integration Caveats

- Some MPI command lines are slightly different; the differences for each are described.

### 5.2.1.2 Integrating an MPI on the Fly

The PBS administrator can perform the steps to integrate the supported MPIs. For non-integrated MPIs, you can integrate them on the fly. You integrate Intel MPI 4.0.3 using environment variables; see [section 5.2.5, “Intel MPI 4.0.3 On Linux with PBS”, on page 85](#). For the rest, you integrate them using the `pbs_tmsh` command.

#### 5.2.1.2.i Integrating an MPI on the Fly using the `pbs_tmsh` Command

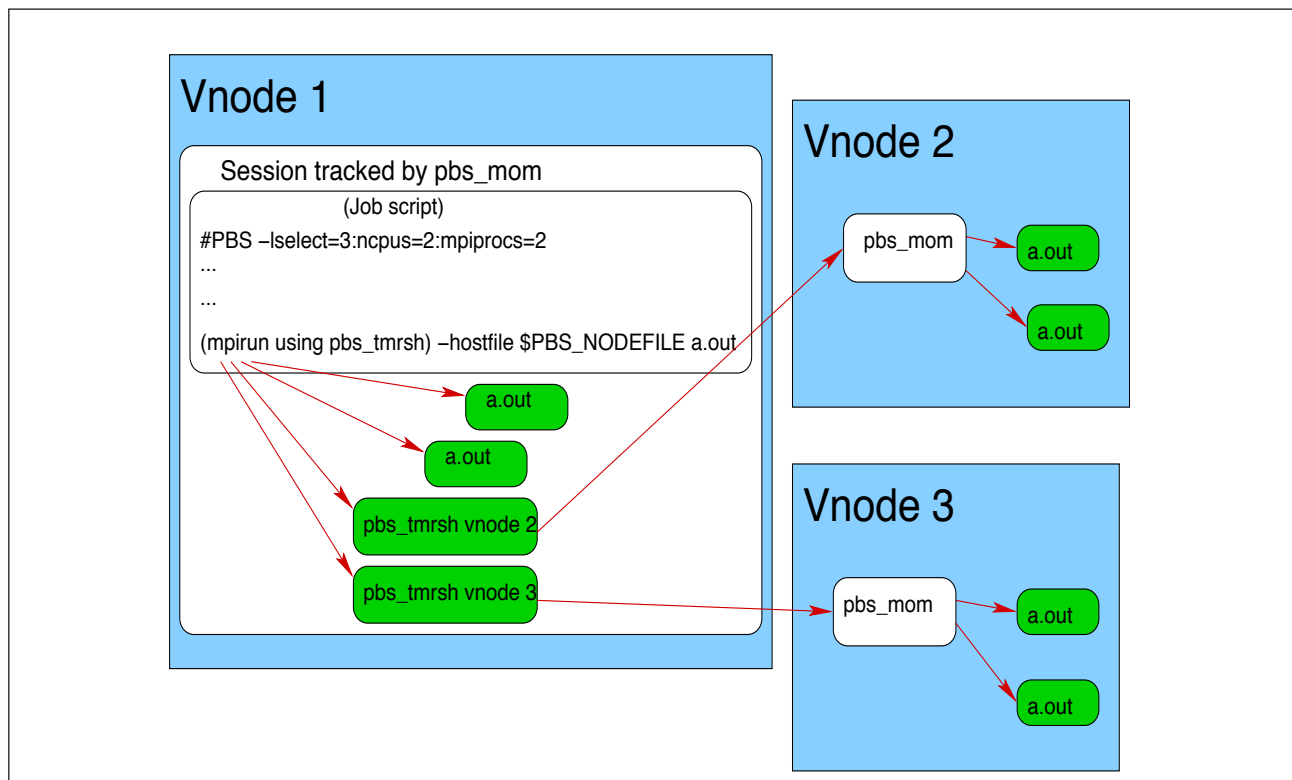

You should not use `pbs_tmsh` with an integrated MPI or with Intel MPI 4.0.3.

This command emulates `rsh`, but uses the PBS TM interface to talk directly to `pbs_mom` on sister vnodes. The `pbs_tmsh` command informs the primary and sister MoMs about job processes on sister vnodes. When the job uses `pbs_tmsh`, PBS can track resource usage for all job processes.

You use `pbs_tmsh` as your `rsh` or `ssh` command. To use `pbs_tmsh`, set the appropriate environment variable to `pbs_tmsh`. For example, to integrate MPICH, set the `P4_RSHCOMMAND` environment variable to `pbs_tmsh`, and to integrate HP MPI, set `MPI_REMSH` to `pbs_tmsh`.

The following figure illustrates how the `pbs_tmsh` command can be used to integrate an MPI on the fly:

Figure 5-1: PBS knows about processes on vnodes 2 and 3, because `pbs_tmsh` talks directly to `pbs_mom`, and `pbs_mom` starts the processes on vnodes 2 and 3

### 5.2.1.2.ii Caveats for the `pbs_tmsh` Command

- This command cannot be used outside of a PBS job; if used outside a PBS job, this command will fail.
- The `pbs_tmsh` command does not perform exactly like `rsh`. For example, you cannot pipe output from `pbs_tmsh`; this will fail.

## 5.2.2 Prerequisites to Using MPI with PBS

The MPI that you intend to use with PBS must be working before you try to use it with PBS. You must be able to run an MPI job outside of PBS.

## 5.2.3 Caveats for Using MPIs

Some applications write scratch files to a temporary location. PBS makes a temporary directory available for this, and puts the path in the `TMPDIR` environment variable. The location of the temporary directory is host-dependent. If you are using an MPI other than LAM MPI or Open MPI, and your application needs scratch space, the temporary directory for the job should be consistent across execution hosts. Your PBS administrator can specify a root for the temporary directory on each host using the `$tmpdir` MoM parameter. In this case, the `TMPDIR` environment variable is set to the full path of the resulting temporary directory. Do not attempt to set `TMPDIR`.

## 5.2.4 HP MPI with PBS

HP MPI can be integrated with PBS on Linux so that PBS can track resource usage, signal processes, and perform accounting, for all job processes. Your PBS administrator can integrate HP MPI with PBS.

### 5.2.4.1 Setting up Your Environment for HP MPI

In order to override the default `rsh`, set `PBS_RSHCOMMAND` in your job script:

```
export PBS_RSHCOMMAND=<rsh choice>
```

### 5.2.4.2 Using HP MPI with PBS

You can run jobs under PBS using HP MPI without making any changes to your MPI command line.

### 5.2.4.3 Options

When running a PBS HP MPI job, you can use the same arguments to the `mpi.run` command as you would outside of PBS. The following options are treated differently under PBS:

```
-h <host>
 Ignored
-l <user>
 Ignored
-np <number>
 Modified to fit the available resources
```

### 5.2.4.4 Caveats for HP MPI with PBS

Under the integrated HP MPI, the job's working directory is changed to your home directory.

## 5.2.5 Intel MPI 4.0.3 On Linux with PBS

If your PBS administrator has integrated Intel MPI 4.0.3 on Linux with PBS, you can use its `mpirun` exactly the same way inside and outside of a PBS job.

The default process manager for Intel MPI 4.0.3 on Linux is Hydra.

## 5.2.6 Intel MPI 4.0.3 On Windows with PBS

On Windows PBS supplies a wrapper script for Intel MPI called `pbs_intelmpi_mpirun.bat`, located in `$PBS_EXEC\bin`. You call this script instead of Intel `mpirun`. All options are passed through the script to `mpirun`.

### 5.2.6.1 Integrating Intel MPI 4.0.3 on the Fly

If you are using Intel MPI 4.0.3 but it has not been integrated with PBS, you can integrate it on the fly by setting environment variables:

1. Specify `rsh`:  
`I_MPI_HYDRA_BOOTSTRAP=rsh`
2. Specify `pbs_tmrsh`.
  - a. If you are running your job entirely on hosts which have `PBS_EXEC/bin` in the default `PATH`, set this:  
`I_MPI_HYDRA_BOOTSTRAP_EXEC=pbs_tmrsh`
  - b. If you are running your job entirely on hosts which do not have `PBS_EXEC/bin` in the default `PATH`, include the full path in the environment variable. For example:  
`I_MPI_HYDRA_BOOTSTRAP_EXEC=/opt/pbs/bin/pbs_tmrsh`

## 5.2.7 Intel MPI 2.0.022, 3, and 4 with PBS

PBS provides an interface to Intel MPI `mpirun` for these versions. If executed inside a PBS job, this allows PBS to track all Intel MPI processes so that PBS can perform accounting and have complete job control. If executed outside of a PBS job, it behaves exactly as if standard Intel MPI `mpirun` was used.

### 5.2.7.1 Using Intel MPI 2.0.022, 3, or 4 Integrated with PBS

You use the same `mpirun` command as you would use outside of PBS.

When submitting PBS jobs that invoke the PBS-supplied interface to `mpirun` for Intel MPI, be sure to explicitly specify the actual number of ranks or MPI tasks in the `qsub select` specification. Otherwise, jobs will fail to run with "too few entries in the machinefile".

For an example of this problem, specification of the following:

```
#PBS -l select=1:ncpus=1:host=hostA+1:ncpus=2:host=hostB
mpirun -np 3 /tmp/mytask
```

results in the following node file:

```
hostA
hostB
```

which conflicts with the "`-np 3`" specification in `mpirun` since only two MPD daemons are started.

The correct way is to specify either of the following:

```
#PBS -l select=1:ncpus=1:host=hostA+2:ncpus=1:host=hostB
#PBS -l select=1:ncpus=1:host=hostA+1:ncpus=2:host=hostB:mpiprocs=2
```

which causes the node file to contain:

```
hostA
hostB
hostB
```

and is consistent with "mpirun -np 3".

### 5.2.7.2 Options to Integrated Intel MPI 2.0.022, 3, or 4

If executed inside a PBS job script, all of the options to the PBS interface are the same as for Intel MPI's `mpirun` except for the following:

#### -host, -ghost

For specifying the execution host to run on. Ignored.

#### -machinefile <file>

The file argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

#### mpdboot option --totalnum=\*

Ignored and replaced by the number of unique entries in `$PBS_NODEFILE`.

#### mpdboot option --file=\*

Ignored and replaced by the name of `$PBS_NODEFILE`. The argument to this option is replaced by `$PBS_NODEFILE`.

Argument to `mpdboot option -f <mpd_hosts_file>` replaced by `$PBS_NODEFILE`.

#### -s

If the PBS interface to Intel MPI's `mpirun` is called inside a PBS job, Intel MPI's `mpirun -s` argument to `mpdboot` is not supported as this closely matches the `mpirun option "-s <spec>".` You can simply run a separate `mpdboot -s` before calling `mpirun`. A warning message is issued by the PBS interface upon encountering a `-s` option describing the supported form.

#### -np

If you do not specify a `-np` option, then no default value is provided by the PBS interface. It is up to the standard `mpirun` to decide what the reasonable default value should be, which is usually `1`. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

### 5.2.7.3 MPD Startup and Shutdown

Intel MPI's `mpirun` takes care of starting and stopping the MPD daemons. The PBS interface to Intel MPI's `mpirun` always passes the arguments `-totalnum=<number of mpds to start>` and `-file=<mpd_hosts_file>` to the actual `mpirun`, taking its input from unique entries in `$PBS_NODEFILE`.

### 5.2.7.4 Examples

Example 5-15: Run a single-executable Intel MPI job with six processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

Node file:

```
pbs-host1
pbs-host1
pbs-host2
pbs-host2
pbs-host3
pbs-host3
```

Job script:

```
mpirun takes care of starting the MPD
daemons on unique hosts listed in
$PBS_NODEFILE, and also runs the 6 processes
on the 6 hosts listed in
$PBS_NODEFILE; mpirun takes care of
shutting down MPDs.
mpirun /path/myprog.x 1200
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

Example 5-16: Run an Intel MPI job with multiple executables on multiple hosts using \$PBS\_NODEFILE and mpiexec arguments to mpirun:

\$PBS\_NODEFILE:

```
hostA
hostA
hostB
hostB
hostC
hostC
```

Job script:

```
mpirun runs MPD daemons on hosts listed in $PBS_NODEFILE
mpirun runs 2 instances of mpitest1
on hostA; 2 instances of mpitest2 on
hostB; 2 instances of mpitest3 on hostC.
mpirun takes care of shutting down the
MPDs at the end of MPI job run.
mpirun -np 2 /tmp/mpitest1 : -np 2 /tmp/mpitest2 : -np 2 /tmp/mpitest3
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

Example 5-17: Run an Intel MPI job with multiple executables on multiple hosts via the `-configfile` option and `$PBS_NODEFILE`:

`$PBS_NODEFILE`:

```
hostA
hostA
hostB
hostB
hostC
hostC
```

Job script:

```
echo "-np 2 /tmp/mpitest1" >> my_config_file
echo "-np 2 /tmp/mpitest2" >> my_config_file
echo "-np 2 /tmp/mpitest3" >> my_config_file

mpirun takes care of starting the MPD daemons
config file says run 2 instances of mpitest1
on hostA; 2 instances of mpitest2 on
hostB; 2 instances of mpitest3 on hostC.
mpirun takes care of shutting down the MPD daemons.
mpirun -configfile my_config_file

cleanup
rm -f my_config_file
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

### 5.2.7.5 Restrictions

The maximum number of ranks that can be launched under integrated Intel MPI is the number of entries in `$PBS_NODEFILE`.

## 5.2.8 LAM MPI with PBS

LAM MPI can be integrated with PBS on Linux so that PBS can track resource usage, signal processes, and perform accounting, for all job processes. Your PBS administrator can integrate LAM MPI with PBS.

Support for LAM MPI is **deprecated**.

### 5.2.8.1 Using LAM 7.x with PBS

You can run jobs under PBS using LAM 7.x without making any changes to your `mpirun` call.

## 5.2.8.2 Using LAM 6.5.9 with PBS

You can run jobs under PBS using LAM 6.5.9.

### 5.2.8.2.i Caveats for LAM 6.5.9 with PBS

- If you specify the `bhost` argument, PBS will print a warning saying that the `bhost` argument is ignored by PBS.
- If you do not specify the `where` argument, `pbs_mpirun` will try to run the your program on all available CPUs using the `C` keyword.

## 5.2.8.3 Example Job Submission Script

The following is a simple PBS job script for use with LAM MPI:

```
#!/bin/bash

Job Name
#PBS -N LamSubTest
Merge output and error files
#PBS -j oe
Select 2 nodes with 1 CPU each
#PBS -l select=2:ncpus=1
Export Users Environmental Variables to Execution Host
#PBS -V
Send email on abort, begin and end
#PBS -m abe
Specify mail recipient
#PBS -M username@example.com

cd $PBS_O_WORKDIR

date
lamboot -v $PBS_NODEFILE
mpirun -np $(cat $PBS_NODEFILE|wc -l) ./ANY_C_MPI_CODE HERE
date
```

When using the integrated `lamboot` in a job script, `lamboot` takes input from `$PBS_NODEFILE` automatically, so the argument is not necessary.

## 5.2.9 MPICH-P4 with PBS

The wrapper is **deprecated**. MPICH-P4 can be integrated with PBS on Linux so that PBS can track resource usage, signal processes, and perform accounting, for all job processes. Your PBS administrator can integrate MPICH-P4 with PBS.

### 5.2.9.1 Options for MPICH-P4 with PBS

Under PBS, the syntax and arguments for the MPICH-P4 `mpirun` command on Linux are the same except for one option, which you should not set:

`-machinefile <file>`

PBS supplies the machinefile. If you try to specify it, PBS prints a warning that it is replacing the machinefile.

### 5.2.9.2 Example of Using MPICH-P4 with PBS

Example of using `mpirun`:

```
#PBS -l select=arch=linux
#
mpirun a.out
```

### 5.2.9.3 MPICH Under Windows

Under Windows, you may need to use the `-localroot` option to MPICH's `mpirun` command in order to allow the job's processes to run more efficiently, or to get around the error "failed to communicate with the barrier command". Here is an example job script:

```
C:\DOCUME~1\user1>type job.scr
echo begin
type %PBS_NODEFILE%
"\Program Files\MPICH\mpd\bin\mpirun" -localroot -np 2 -machinefile %PBS_NODEFILE%
\winnt\temp\netpipe -reps 3
echo done
```

#### 5.2.9.3.i Caveats for MPICH Under Windows

Under Windows, MPICH is not integrated with PBS. Therefore, PBS is limited to tracking and controlling processes and performing accounting only for job processes on the primary vnode.

## 5.2.10 MPICH-GM with PBS

### 5.2.10.1 Using MPICH-GM and MPD with PBS

The wrapper is **deprecated**. PBS provides an interface to MPICH-GM's `mpirun` using MPD. If executed inside a PBS job, this allows for PBS to track all MPICH-GM processes started by the MPD daemons so that PBS can perform accounting and have complete job control. If executed outside of a PBS job, it behaves exactly as if standard `mpirun` with MPD had been used.

You use the same `mpirun` command as you would use outside of PBS. If the MPD daemons are not already running, the PBS interface will take care of starting them for you.

#### 5.2.10.1.i Options

Inside a PBS job script, all of the options to the PBS interface are the same as `mpirun` with MPD except for the following:

`-m <file>`

The `file` argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

`-np`

If not specified, the number of entries found in `$PBS_NODEFILE` is used. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

`-pg`

The use of the `-pg` option, for having multiple executables on multiple hosts, is allowed but it is up to you to make sure only PBS hosts are specified in the process group file; MPI processes spawned on non-PBS hosts are not guaranteed to be under the control of PBS.

### 5.2.10.1.ii MPD Startup and Shutdown

The script starts MPD daemons on each of the unique hosts listed in `$PBS_NODEFILE`, using either the `rsh` or `ssh` method based on the value of the environment variable `RSHCOMMAND`. The default is `rsh`. The script also takes care of shutting down the MPD daemons at the end of a run.

If the MPD daemons are not running, the PBS interface to `mpirun` will start GM's MPD daemons as you on the allocated PBS hosts. The MPD daemons may have been started already by the administrator or by you. MPD daemons are not started inside a PBS prologue script since it won't have the path of `mpirun` that you executed (GM or MX), which would determine the path to the MPD binary.

### 5.2.10.1.iii Examples

Example 5-18: Run a single-executable MPICH-GM job with 3 processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

```
$PBS_NODEFILE:
pbs-host1
pbs-host2
pbs-host3
qsub -l select=3:ncpus=1
[MPICH-GM-HOME]/bin/mpirun -np 3 /path/myprog.x 1200
^D
<job-id>
```

If the GM MPD daemons are not running, the PBS interface to `mpirun` will start them as you on the allocated PBS hosts. The daemons may have been previously started by the administrator or by you.

Example 5-19: Run an MPICH-GM job with multiple executables on multiple hosts listed in the process group file `procgrp`:

```
Job script:
qsub -l select=2:ncpus=1
echo "host1 1 user1 /x/y/a.exe arg1 arg2" > procgrp
echo "host2 1 user1 /x/x/b.exe arg1 arg2" >> procgrp

[MPICH-GM-HOME]/bin/mpirun -pg procgrp /path/mypro.x 1200
rm -f procgrp
^D
<job-id>
```

When the job runs, `mpirun` gives the warning message:

```
warning: "-pg" is allowed but it is up to user to make sure only PBS hosts are specified; MPI
processes spawned are not guaranteed to be under PBS-control.
```

The warning is issued because if any of the hosts listed in `procgrp` are not under the control of PBS, then the processes on those hosts will not be under the control of PBS.

## 5.2.10.2 Using MPICH-GM and `rsh/ssh` with PBS

PBS provides an interface to MPICH-GM's `mpirun` using `rsh/ssh`. If executed inside a PBS job, this lets PBS track all MPICH-GM processes started via `rsh/ssh` so that PBS can perform accounting and have complete job control. If executed outside of a PBS job, it behaves exactly as if standard `mpirun` had been used.

You use the same `mpirun` command as you would use outside of PBS.

### 5.2.10.2.i Options

Inside a PBS job script, all of the options to the PBS interface are the same as `mpirun` except for the following:

**-machinefile <file>**

The `file` argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

**-np**

If not specified, the number of entries found in `$PBS_NODEFILE` is used. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

**-pg**

The use of the `-pg` option, for having multiple executables on multiple hosts, is allowed but it is up to you to make sure only PBS hosts are specified in the process group file; MPI processes spawned on non-PBS hosts are not guaranteed to be under the control of PBS.

### 5.2.10.2.ii Examples

Example 5-20: Run a single-executable MPICH-GM job with 64 processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

`$PBS_NODEFILE:`

```
pbs-host1
pbs-host2
...
pbs-host64
```

```
qsub -l select=64:ncpus=1 -l place=scatter
mpirun -np 64 /path/myprog.x 1200
^D
<job-id>
```

Example 5-21: Run an MPICH-GM job with multiple executables on multiple hosts listed in the process group file `procgrp`:

```
qsub -l select=2:ncpus=1
echo "host1 1 user1 /x/y/a.exe arg1 arg2" > procgrp
echo "host2 1 user1 /x/x/b.exe arg1 arg2" >> procgrp
mpirun -pg procgrp /path/mypro.x
rm -f procgrp
^D
<job-id>
```

When the job runs, `mpirun` gives this warning message:

```
warning: "-pg" is allowed but it is up to user to make sure only PBS hosts are specified; MPI
processes spawned are not guaranteed to be under the control of PBS.
```

The warning is issued because if any of the hosts listed in `procgrp` are not under the control of PBS, then the processes on those hosts will not be under the control of PBS.

## 5.2.10.3 Restrictions

The maximum number of ranks that can be launched under integrated MPICH-GM is the number of entries in `$PBS_NODEFILE`.

## 5.2.11 MPICH-MX with PBS

### 5.2.11.1 Using MPICH-MX and MPD with PBS

The wrapper is **deprecated**. PBS provides an interface to MPICH-MX's `mpirun` using MPD. If executed inside a PBS job, this allows for PBS to track all MPICH-MX processes started by the MPD daemons so that PBS can perform accounting and have complete job control. If executed outside of a PBS job, it behaves exactly as if standard MPICH-MX `mpirun` with MPD was used.

You use the same `mpirun` command as you would use outside of PBS. If the MPD daemons are not already running, the PBS interface will take care of starting them for you.

#### 5.2.11.1.i Options

Inside a PBS job script, all of the options to the PBS interface are the same as `mpirun` with MPD except for the following:

**-m <file>**

The `file` argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

**-np**

If not specified, the number of entries found in `$PBS_NODEFILE` is used. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

**-pg**

The use of the `-pg` option, for having multiple executables on multiple hosts, is allowed but it is up to you to make sure only PBS hosts are specified in the process group file; MPI processes spawned on non-PBS hosts are not guaranteed to be under the control of PBS.

#### 5.2.11.1.ii MPD Startup and Shutdown

The PBS `mpirun` interface starts MPD daemons on each of the unique hosts listed in `$PBS_NODEFILE`, using either the `rsh` or `ssh` method, based on value of environment variable `RSHCOMMAND`. The default is `rsh`. The interface also takes care of shutting down the MPD daemons at the end of a run.

If the MPD daemons are not running, the PBS interface to `mpirun` starts MX's MPD daemons as you on the allocated PBS hosts. The MPD daemons may already have been started by the administrator or by you. MPD daemons are not started inside a PBS prologue script since it won't have the path of `mpirun` that you executed (GM or MX), which would determine the path to the MPD binary.

#### 5.2.11.1.iii Examples

Example 5-22: Run a single-executable MPICH-MX job with 64 processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

`$PBS_NODEFILE:`

```
pbs-host1
pbs-host2
...
pbs-host64
```

```
qsub -l select=64:ncpus=1 -lplace=scatter
[MPICH-MX-HOME]/bin/mpirun -np 64 /path/myprog.x 1200
^D
<job-id>
```

If the MPD daemons are not running, the PBS interface to `mpirun` starts MX's MPD daemons as you on the allocated PBS hosts. The MPD daemons may be already started by the administrator or by you.

Example 5-23: Run an MPICH-MX job with multiple executables on multiple hosts listed in the process group file `procgrp`:

```
qsub -l select=2:ncpus=1
echo "pbs-host1 1 username /x/y/a.exe arg1 arg2" > procgrp
echo "pbs-host2 1 username /x/x/b.exe arg1 arg2" >> procgrp
[MPICH-MX-HOME]/bin/mpirun -pg procgrp /path/myprog.x 1200
rm -f procgrp
^D
<job-id>
```

`mpirun` prints a warning message:

```
warning: "-pg" is allowed but it is up to user to make sure only PBS hosts are specified; MPI
processes spawned are not guaranteed to be under PBS-control
```

The warning is issued because if any of the hosts listed in `procgrp` are not under the control of PBS, then the processes on those hosts will not be under the control of PBS.

### 5.2.11.2 Using MPICH-MX and `rsh/ssh` with PBS

**Deprecated.** PBS provides an interface to MPICH-MX's `mpirun` using `rsh/ssh`. If executed inside a PBS job, this allows for PBS to track all MPICH-MX processes started by `rsh/ssh` so that PBS can perform accounting and has complete job control. If executed outside of a PBS job, it behaves exactly as if standard `mpirun` had been used.

You use the same `mpirun` command as you would use outside of PBS.

#### 5.2.11.2.i Options

Inside a PBS job script, all of the options to the PBS interface are the same as standard `mpirun` except for the following:

`-machinefile <file>`

The `file` argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

`-np`

If not specified, the number of entries found in the `$PBS_NODEFILE` is used. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

`-pg`

The use of the `-pg` option, for having multiple executables on multiple hosts, is allowed but it is up to you to make sure only PBS hosts are specified in the process group file; MPI processes spawned on non-PBS hosts are not guaranteed to be under the control of PBS.

#### 5.2.11.2.ii Examples

Example 5-24: Run a single-executable MPICH-MX job with 64 processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

```
$PBS_NODEFILE:
pbs-host1
pbs-host2
...
pbs-host64

qsub -l select=64:ncpus=1
mpirun -np 64 /path/myprog.x 1200
^D
<job-id>
```

Example 5-25: Run an MPICH-MX job with multiple executables on multiple hosts listed in the process group file `procgrp`:

```
qsub -l select=2:ncpus=1
echo "pbs-host1 1 username /x/y/a.exe arg1 arg2" > procgrp
echo "pbs-host2 1 username /x/x/b.exe arg1 arg2" >> procgrp
mpirun -pg procgrp /path/myprog.x
rm -f procgrp
^D
<job-id>
```

`mpirun` prints the warning message:

```
warning: "-pg" is allowed but it is up to user to make sure only PBS hosts are specified; MPI
processes spawned are not guaranteed to be under PBS-control
```

The warning is issued because if any of the hosts listed in `procgrp` are not under the control of PBS, then the processes on those hosts will not be under the control of PBS.

### 5.2.11.3 Restrictions

The maximum number of ranks that can be launched under integrated MPICH-MX is the number of entries in `$PBS_NODEFILE`.

## 5.2.12 MPICH2 with PBS on Linux

On Linux, PBS provides an interface to MPICH2's `mpirun`. If executed inside a PBS job, this allows for PBS to track all MPICH2 processes so that PBS can perform accounting and have complete job control. If executed outside of a PBS job, it behaves exactly as if standard MPICH2's `mpirun` had been used.

You use the same `mpirun` command as you would use outside of PBS.

When submitting PBS jobs under the PBS interface to MPICH2's `mpirun`, be sure to explicitly specify the actual number of ranks or MPI tasks in the `qsub select` specification. Otherwise, jobs will fail to run with "too few entries in the machinefile".

For instance, the following erroneous specification:

```
#PBS -l select=1:ncpus=1:host=hostA+1:ncpus=2:host=hostB
mpirun -np 3 /tmp/mytask
```

results in this `$PBS_NODEFILE` listing:

```
hostA
hostB
```

which conflicts with the "`-np 3`" specification in `mpirun` as only two MPD daemons are started.

The correct way is to specify either of the following:

```
#PBS -l select=1:ncpus=1:host=hostA+2:ncpus=1:host=hostB
#PBS -l select=1:ncpus=1:host=hostA+1:ncpus=2:host=hostB:mpiprocs=2
```

which causes `$PBS_NODEFILE` to contain:

```
hostA
hostB
hostB
```

and this is consistent with "`mpirun -np 3`".

### 5.2.12.1 Options

If executed inside a PBS job script, all of the options to the PBS interface are the same as MPICH2's `mpirun` except for the following:

**-host, -ghost**

For specifying the execution host to run on. Ignored.

**-machinefile <file>**

The file argument contents are ignored and replaced by the contents of `$PBS_NODEFILE`.

**-localonly <number of processes>**

For specifying the *number of processes* to run locally. Not supported. You are advised instead to use the equivalent arguments:

```
"-np <x> -localonly".
```

**-np**

If you do not specify a `-np` option, then no default value is provided by the PBS interface to MPICH2. It is up to the standard `mpirun` to decide what the reasonable default value should be, which is usually 1. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

### 5.2.12.2 MPD Startup and Shutdown

The interface ensures that the MPD daemons are started on each of the hosts listed in `$PBS_NODEFILE`. It also ensures that the MPD daemons are shut down at the end of MPI job execution.

### 5.2.12.3 Examples

Example 5-26: Run a single-executable MPICH2 job with six processes spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`. Only three hosts are available:

`$PBS_NODEFILE`:

```
pbs-host1
pbs-host2
pbs-host3
pbs-host1
pbs-host2
pbs-host3
```

Job.script:

```
mpirun runs 6 processes, scattered over 3 hosts
listed in $PBS_NODEFILE
mpirun -np 6 /path/myprog.x 1200
```

Run job script:

```
qsub -l select=6:ncpus=1 -lplace = scatter job.script
<job-id>
```

Example 5-27: Run an MPICH2 job with multiple executables on multiple hosts using \$PBS\_NODEFILE and mpiexec arguments in mpirun:

\$PBS\_NODEFILE:

```
hostA
hostA
hostB
hostB
hostC
hostC
```

Job script:

```
#PBS -l select=3:ncpus=2:mpiprocs=2
mpirun -np 2 /tmp/mpitest1 : -np 2 /tmp/mpitest2 : -np 2 /tmp/mpitest3
```

Run job:

```
qsub job.script
```

Example 5-28: Run an MPICH2 job with multiple executables on multiple hosts using mpirun -configfile option and \$PBS\_NODEFILE:

\$PBS\_NODEFILE:

```
hostA
hostA
hostB
hostB
hostC
hostC
```

Job script:

```
#PBS -l select=3:ncpus=2:mpiprocs=2
echo "-np 2 /tmp/mpitest1" > my_config_file
echo "-np 2 /tmp/mpitest2" >> my_config_file
echo "-np 2 /tmp/mpitest3" >> my_config_file
mpirun -configfile my_config_file
rm -f my_config_file
```

Run job:

```
qsub job.script
```

### 5.2.12.4 Restrictions

The maximum number of ranks that can be launched under integrated MPICH2 is the number of entries in `$PBS_NODEFILE`.

## 5.2.13 MPICH2 1.4.1p1 On Windows with PBS

On Windows PBS supplies a wrapper script for MPICH2 1.4.1p1 called `pbs_mpich2_mpirun.bat`, located in `$PBS_EXEC\bin`. You call this script instead of MPICH2 `mpirun`. All options are passed through the script to `mpirun`.

## 5.2.14 MVAPICH with PBS

The wrapper is **deprecated**. PBS provides an `mpirun` interface to the MVAPICH `mpirun`. When you use the PBS-supplied `mpirun`, PBS can track all MVAPICH processes, perform accounting, and have complete job control. Your PBS administrator can integrate MVAPICH with PBS so that you can use the PBS-supplied `mpirun` in place of the MVAPICH `mpirun` in your job scripts.

MVAPICH allows your jobs to use InfiniBand.

### 5.2.14.1 Interface to MVAPICH `mpirun` Command

If executed outside of a PBS job, the PBS-supplied interface to `mpirun` behaves exactly as if standard MVAPICH `mpirun` had been used.

If executed inside a PBS job script, all of the options to the PBS interface are the same as MVAPICH's `mpirun` except for the following:

**-map**

The `map` option is ignored.

**-machinefile <file>**

The `machinefile` option is ignored.

**-exclude**

The `exclude` option is ignored.

**-np**

If you do not specify a `-np` option, then PBS uses the number of entries found in `$PBS_NODEFILE`. The maximum number of ranks that can be launched is the number of entries in `$PBS_NODEFILE`.

### 5.2.14.2 Examples

Example 5-29: Run a single-executable MVAPICH job with six ranks spread out across the PBS-allocated hosts listed in `$PBS_NODEFILE`:

---

`$PBS_NODEFILE:`

```
pbs-host1
pbs-host1
pbs-host2
pbs-host2
pbs-host3
pbs-host3
```

Contents of job.script:

```
mpirun runs 6 processes mapped one to each line in $PBS_NODEFILE
mpirun -np 6 /path/myprog
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

### 5.2.14.3 Restrictions

The maximum number of ranks that can be launched under integrated MVAPICH is the number of entries in `$PBS_NODEFILE`.

## 5.2.15 MVAPICH2 with PBS

PBS provides an `mpiexec` interface to MVAPICH2's `mpiexec`. When you use the PBS-supplied `mpiexec`, PBS can track all MVAPICH2 processes, perform accounting, and have complete job control. Your PBS administrator can integrate MVAPICH2 with PBS so that you can use the PBS-supplied `mpirun` in place of the MVAPICH2 `mpirun` in your job scripts.

MVAPICH2 allows your jobs to use InfiniBand.

### 5.2.15.1 Interface to MVAPICH2 `mpiexec` Command

If executed outside of a PBS job, it behaves exactly as if standard MVAPICH2's `mpiexec` had been used.

If executed inside a PBS job script, all of the options to the PBS interface are the same as MVAPICH2's `mpiexec` except for the following:

`-host`

The `host` option is ignored.

`-machinefile <file>`

The `file` option is ignored.

`-mpdboot`

If `mpdboot` is not called before `mpiexec`, it is called automatically before `mpiexec` runs so that an MPD daemon is started on each host assigned by PBS.

### 5.2.15.2 MPD Startup and Shutdown

The interface ensures that the MPD daemons are started on each of the hosts listed in `$PBS_NODEFILE`. It also ensures that the MPD daemons are shut down at the end of MPI job execution.

### 5.2.15.3 Examples

Example 5-30: Run a single-executable MVAPICH2 job with six ranks on hosts listed in `$PBS_NODEFILE`:

`$PBS_NODEFILE:`

```
pbs-host1
pbs-host1
pbs-host2
pbs-host2
pbs-host3
pbs-host3
```

Job.script:

```
mpiexec -np 6 /path/mpiprogram
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

Example 5-31: Launch an MVAPICH2 MPI job with multiple executables on multiple hosts listed in the default file `"mpd.hosts"`. Here, run executables `prog1` and `prog2` with two ranks of `prog1` on `host1`, two ranks of `prog2` on `host2` and two ranks of `prog2` on `host3`, all specified on the command line:

`$PBS_NODEFILE:`

```
pbs-host1
pbs-host1
pbs-host2
pbs-host2
pbs-host3
pbs-host3
```

Job.script:

```
mpiexec -n 2 prog1 : -n 2 prog2 : -n 2 prog2
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

Example 5-32: Launch an MVAPICH2 MPI job with multiple executables on multiple hosts listed in the default file `"mpd.hosts"`. Run executables `prog1` and `prog2` with two ranks of `prog1` on `host1`, two ranks of `prog2` on `host2` and two ranks of `prog2` on `host3`, all specified using the `-configfile` option:

```
$PBS_NODEFILE:
```

```
pbs-host1
pbs-host1
pbs-host2
pbs-host2
pbs-host3
pbs-host3
```

Job.script:

```
echo "-n 2 -host host1 prog1" > /tmp/jobconf
echo "-n 2 -host host2 prog2" >> /tmp/jobconf
echo "-n 2 -host host3 prog2" >> /tmp/jobconf
mpiexec -configfile /tmp/jobconf
rm /tmp/jobconf
```

Run job script:

```
qsub -l select=3:ncpus=2:mpiprocs=2 job.script
<job-id>
```

#### 5.2.15.4 Restrictions

The maximum number of ranks that can be launched under MVAPICH2 is the number of entries in `$PBS_NODEFILE`.

### 5.2.16 Open MPI with PBS

Open MPI can be integrated with PBS on Linux so that PBS can track resource usage, signal processes, and perform accounting, for all job processes. Your PBS administrator can integrate Open MPI with PBS.

#### 5.2.16.1 Using Open MPI with PBS

You can run jobs under PBS using Open MPI without making any changes to your MPI command line.

### 5.2.17 Platform MPI with PBS

Platform MPI can be integrated with PBS on Linux so that PBS can track resource usage, signal processes, and perform accounting, for all job processes. Your PBS administrator can integrate Platform MPI with PBS.

#### 5.2.17.1 Using Platform MPI with PBS

You can run jobs under PBS using Platform MPI without making any changes to your MPI command line.

#### 5.2.17.2 Setting up Your Environment

In order to override the default `rsh`, set `PBS_RSHCOMMAND` in your job script:

```
export PBS_RSHCOMMAND=<rsh command>
```

## 5.2.18 HPE MPI with PBS

PBS supplies its own `mpiexec` to use with HPE MPI on a multi-vnode machine running supported versions of HPE MPI. When you use the PBS-supplied `mpiexec`, PBS can track resource usage, signal processes, and perform accounting, for all job processes. The PBS `mpiexec` provides the standard `mpiexec` interface.

See your PBS administrator to find out whether your system is configured for the PBS `mpiexec`.

### 5.2.18.1 Using HPE MPI with PBS

You can launch an MPI job on a single HPE system, or across multiple HPE systems. For MPI jobs across multiple HPE systems, PBS will manage the multi-host jobs. For example, if you have two HPE systems named `host1` and `host2`, and want to run two applications called `mympi1` and `mympi2` on them, you can put this in your job script:

```
mpiexec -host host1 -n 4 mympi1 : -host host2 -n 8 mympi2
```

PBS will manage and track the job's processes. When the job is finished, PBS will clean up after it.

You can run MPI jobs in the placement sets chosen by PBS.

### 5.2.18.2 Prerequisites

In order to use MPI within a PBS job with HPE MPI, you may need to add the following in your job script before you call MPI:

```
module load mpt
```

### 5.2.18.3 Fitting Jobs onto Nodeboards

PBS will try to put a job that fits in a single nodeboard on just one nodeboard. However, if the only CPUs available are on separate nodeboards, and those vnodes are not allocated exclusively to existing jobs, and the job can share a vnode, then the job is run on the separate nodeboards.

### 5.2.18.4 Checkpointing and Suspending Jobs

Jobs are suspended on the HPE systems using the PBS `suspend` feature.

Jobs are checkpointed on HPE systems using application-level checkpointing. There is no OS-level checkpoint.

Suspended or checkpointed jobs will resume on the original nodeboards.

### 5.2.18.5 Using CSA

PBS support for CSA on HPE systems is no longer available. The CSA functionality for HPE systems has been **removed** from PBS.

## 5.3 Using PVM with PBS

You use the `pvmexec` command to execute a Parallel Virtual Machine (PVM) program. PVM is not integrated with PBS; PBS is limited to monitoring, controlling, and accounting for job processes only on the primary vnode.

### 5.3.1 Arguments to `pvmexec` Command

The `pvmexec` command expects a `hostfile` argument for the list of hosts on which to spawn the parallel job.

### 5.3.2 Using PVM Daemons

To start the PVM daemons on the hosts listed in `$PBS_NODEFILE`:

1. Start the PVM console on the first host in the list
2. Print the hosts to the standard output file named `jobname.o<PBS job ID>`:

```
echo conf | pvm $PBS_NODEFILE
```

To quit the PVM console but leave the PVM daemons running:

```
quit
```

To stop the PVM daemons, restart the PVM console, and quit:

```
echo halt | pvm
```

### 5.3.3 Submitting a PVM Job

To submit a PVM job to PBS, use the following:

```
qsub <job script>
```

### 5.3.4 Examples

Example 5-33: To submit a PVM job to PBS, use the following:

```
qsub your_pvm_job
```

Here is an example script for `your_pvm_job`:

```
#PBS -N pvmjob
#PBS -V
cd $PBS_O_WORKDIR
echo conf | pvm $PBS_NODEFILE
echo quit | pvm
./my_pvm_program
echo halt | pvm
```

Example 5-34: Sample PBS script for a PVM job:

```
#PBS -N pvmjob
#
pvmexec a.out -inputfile data_in
```

## 5.4 Using OpenMP with PBS

PBS Professional supports OpenMP applications by setting the `OMP_NUM_THREADS` variable in the job's environment, based on the resource request of the job. The OpenMP run-time picks up the value of `OMP_NUM_THREADS` and creates threads appropriately.

MoM sets the value of `OMP_NUM_THREADS` based on the first chunk of the `select` statement. If you request `ompthreads` in the first chunk, MoM sets the environment variable to the value of `ompthreads`. If you do not request `ompthreads` in the first chunk, then `OMP_NUM_THREADS` is set to the value of the `ncpus` resource of that chunk. If you do not request either `ncpus` or `ompthreads` for the first chunk of the `select` statement, then `OMP_NUM_THREADS` is set to 1.

You cannot directly set the value of the `OMP_NUM_THREADS` environment variable; MoM will override any setting you attempt.

See [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#) for a definition of the `ompthreads` resource.

Example 5-35: Submit an OpenMP job as a single chunk, for a two-CPU, two-thread job requiring 10gb of memory:

```
qsub -l select=1:ncpus=2:mem=10gb
```

Example 5-36: Run an MPI application with 64 MPI processes, and one thread per process:

```
#PBS -l select=64:ncpus=1
mpiexec -n 64 ./a.out
```

Example 5-37: Run an MPI application with 64 MPI processes, and four OpenMP threads per process:

```
#PBS -l select=64:ncpus=4
mpiexec -n 64 omlace -nt 4 ./a.out
or
#PBS -l select=64:ncpus=4:ompthreads=4
mpiexec -n 64 omlace -nt 4 ./a.out
```

## 5.4.1 Running Fewer Threads than CPUs

You might be running an OpenMP application on a host and wish to run fewer threads than the number of CPUs requested. This might be because the threads need exclusive access to shared resources in a multi-core processor system, such as to a cache shared between cores, or to the memory shared between cores.

Example 5-38: You want one chunk, with 16 CPUs and eight threads:

```
qsub -l select=1:ncpus=16:ompthreads=8
```

## 5.4.2 Running More Threads than CPUs

You might be running an OpenMP application on a host and wish to run more threads than the number of CPUs requested, perhaps because each thread is I/O bound.

Example 5-39: You want one chunk, with eight CPUs and 16 threads:

```
qsub -l select=1:ncpus=8:ompthreads=16
```

## 5.4.3 Caveats for Using OpenMP with PBS

Make sure that you request the correct number of MPI ranks for your job, so that the PBS node file contains the correct number of entries. See [section 5.1.3, “Specifying Number of MPI Processes Per Chunk”, on page 78](#).

## 5.5 Hybrid MPI-OpenMP Jobs

For jobs that are both MPI and multi-threaded, the number of threads per chunk, for all chunks, is set to the number of threads requested (explicitly or implicitly) in the first chunk, except for MPIs that have been integrated with the PBS TM API.

For MPIs that are integrated with the PBS TM interface, (LAM MPI and Open MPI), you can specify the number of threads separately for each chunk, by specifying the `ompthreads` resource separately for each chunk.

For most MPIs, the `OMP_NUM_THREADS` and `NCPUS` environment variables default to the number of `ncpus` requested for the first chunk.

Should you have a job that is both MPI and multi-threaded, you can request one chunk for each MPI process, or set `mpiprocs` to the number of MPI processes you want on each chunk. See [section 5.1.3, “Specifying Number of MPI Processes Per Chunk”](#), on page 78.

### 5.5.1 Examples

Example 5-40: To request four chunks, each with one MPI process, two CPUs and two threads:

```
qsub -l select=4:ncpus=2
```

or

```
qsub -l select=4:ncpus=2:ompthreads=2
```

Example 5-41: To request four chunks, each with two CPUs and four threads:

```
qsub -l select=4:ncpus=2:ompthreads=4
```

Example 5-42: To request 16 MPI processes each with two threads on machines with two processors:

```
qsub -l select=16:ncpus=2
```

Example 5-43: To request two chunks, each with eight CPUs and eight MPI tasks and four threads:

```
qsub -l select=2:ncpus=8:mpiprocs=8:ompthreads=4
```

Example 5-44: For the following:

```
qsub -l select=4:ncpus=2
```

This request is satisfied by four CPUs from VnodeA, two from VnodeB and two from VnodeC, so the following is written to `$PBS_NODEFILE`:

```
VnodeA
VnodeA
VnodeB
VnodeC
```

The OpenMP environment variables are set, for the four PBS tasks corresponding to the four MPI processes, as follows:

- For PBS task #1 on VnodeA: `OMP_NUM_THREADS=2 NCPUS=2`
- For PBS task #2 on VnodeA: `OMP_NUM_THREADS=2 NCPUS=2`
- For PBS task #3 on VnodeB: `OMP_NUM_THREADS=2 NCPUS=2`
- For PBS task #4 on VnodeC: `OMP_NUM_THREADS=2 NCPUS=2`

Example 5-45: For the following:

```
qsub -l select=3:ncpus=2:mpiprocs=2:ompthreads=1
```

---

This is satisfied by two CPUs from each of three vnodes (VnodeA, VnodeB, and VnodeC), so the following is written to `$PBS_NODEFILE`:

```
VnodeA
VnodeA
VnodeB
VnodeB
VnodeC
VnodeC
```

The OpenMP environment variables are set, for the six PBS tasks corresponding to the six MPI processes, as follows:

- For PBS task #1 on VnodeA: `OMP_NUM_THREADS=1 NCPUS=1`
- For PBS task #2 on VnodeA: `OMP_NUM_THREADS=1 NCPUS=1`
- For PBS task #3 on VnodeB: `OMP_NUM_THREADS=1 NCPUS=1`
- For PBS task #4 on VnodeB: `OMP_NUM_THREADS=1 NCPUS=1`
- For PBS task #5 on VnodeC: `OMP_NUM_THREADS=1 NCPUS=1`
- For PBS task #6 on VnodeC: `OMP_NUM_THREADS=1 NCPUS=1`

Example 5-46: To run two threads on each of *N* chunks, each running a process, all on the same HPE system:

```
qsub -l select=N:ncpus=2 -l place=pack
```

This starts *N* processes on a single host, with two OpenMP threads per process, because `OMP_NUM_THREADS=2`.

# Controlling How Your Job Runs

## 6.1 Using Job Exit Status

PBS can use the exit status of your job as input to the epilogue, and to determine whether to run a dependent job. If you are running under Linux, make sure that your job's exit status is captured correctly; see [section 1.4.2.4, “Capture Correct Job Exit Status”, on page 6](#).

Job exit codes are listed in [section 13.9, “Job Exit Status Codes”, on page 509 of the PBS Professional Administrator's Guide](#).

The exit status of a job array is determined by the status of each of its completed subjobs, and is only available when all valid subjobs have completed. The individual exit status of a completed subjob is passed to the epilogue, and is available in the ‘E’ accounting log record of that subjob. See [“Job Array Exit Status” on page 156](#).

### 6.1.1 Caveats for Exit Status

- Normally, `qsub` exits with the exit status for a blocking job, but if you submit a job that is both blocking and interactive, PBS does not return the job's exit status. See [section 6.10, “Making qsub Wait Until Job Ends”, on page 120](#).
- For a blocking job, the exit status is returned before staging finishes. See [section 6.10.2, “Caveats for Blocking Jobs”, on page 121](#).
- The exit status of an interactive job is always recorded as 0 (zero), regardless of the actual exit status.

## 6.2 Using Job Dependencies

PBS allows you to specify dependencies between two or more jobs. Dependencies are useful for a variety of tasks, such as:

- Specifying the order in which jobs in a set should execute
- Requesting a job run only if an error occurs in another job
- Holding jobs until a particular job starts or completes execution

There is no limit on the number of dependencies per job.

If you have one or more jobs `j2... jN` that are dependent on a job `j1` so that they can run only after `j1` runs, and you delete `j1`, PBS deletes jobs `j2... jN`. If you have jobs `j2... jN` that can run only after `j1` has not run successfully, and you delete `j1`, PBS releases the dependencies for jobs `j2... jN` so that they can run.

### 6.2.1 Syntax for Job Dependencies

Use the “`-W depend=<dependency list>`” option to `qsub` to define dependencies between jobs. The *dependency list* has the format:

```
<type>:<arg list>[,<type>:<arg list> ...]
```

where except for the `on` type, the *arg list* is one or more PBS job IDs in the form:

```
<job ID>[:<job ID> ...]
```

These are the available dependency types:

**after:<arg list>**

This job may start only after all jobs in *arg list* have started execution.

**afterok:<arg list>**

This job may start only after all jobs in *arg list* have terminated with no errors.

**afternotok:<arg list>**

This job may start only after all jobs in *arg list* have terminated with errors.

**afterany:<arg list>**

This job may start after all jobs in *arg list* have finished execution, with or without errors. This job will not run if a job in the *arg list* was deleted without ever having been run.

**before:<arg list>**

Jobs in *arg list* may start only after specified jobs have begun execution. You must submit jobs that will run before other jobs with a type of **on**.

**beforeok:<arg list>**

Jobs in *arg list* may start only after this job terminates without errors.

**beforenotok:<arg list>**

If this job terminates execution with errors, the jobs in *arg list* may begin.

**beforeany:<arg list>**

Jobs in *arg list* may start only after specified jobs terminate execution, with or without errors. Requires use of **on** dependency for jobs that will run before other jobs.

**on:count**

This job may start only after *count* dependencies on other jobs have been satisfied. This type is used in conjunction with one of the **before** types. *count* is an integer greater than 0.

**runone:<job ID>**

(2020.1 Beta) Puts the current job and the job with *job ID* in a set of jobs out of which PBS will eventually run just one. To add a job to a set, specify the job ID of another job already in the set.

The **depend** job attribute controls job dependencies. You can set it using the **qsub** command line or a PBS directive:

```
qsub -W depend=...
#PBS depend=...
```

### 6.2.1.1 Running Your Job on First Available Resources (2020.1 Beta)

**2020.1 Beta.** This feature is subject to drastic change or removal without notice in future releases.

You may want to run a job on whichever resources become available first, even if the job could run on other sets of resources. You may want to start a flexible job as soon as possible on a smaller set of resources rather than waiting longer for a larger set of resources, or you may prefer certain resources but be able to use others (for example, you might prefer a specific processor, but still be able to run on another if that is all that's available).

If you submit a set of jobs where each job has a “runone” dependency on the others, PBS runs only one of the jobs in the “runone set”. PBS automatically groups the jobs into a runone set. The jobs in a runone set can run different scripts.

When any of the jobs in the set starts, PBS applies a system hold to the others. The hold on the other jobs is released when the running job is requested:

- Via **qrerun**
- When node fail requeue is triggered

The other jobs in the set are deleted:

- When a job ends, regardless of its exit status
- When the running job is deleted

To identify a job as a member of the set, give it a “runone” dependency on the previously-submitted member of the set. For example, we have three jobs, each of which runs on different resources. To submit these three jobs as a runone set:

```
qsub -lselect=200:ncpus=16 -lwalltime=1:00:00 myscript.sh
10.myserver
qsub -lselect=100:ncpus=16 -lwalltime=2:00:00 -Wdepend=runone:10 myscript.sh
11.myserver
qsub -lselect=50:ncpus=16 -lwalltime=4:00:00 -Wdepend=runone:10 myscript.sh
12.myserver
```

## 6.2.2 Job Dependency Examples

Example 6-1: You have three jobs, job1, job2, and job3, and you want job3 to start *after* job1 and job2 have *ended*:

```
qsub job1
16394.jupiter
qsub job2
16395.jupiter
qsub -W depend=afterany:16394:16395 job3
16396.jupiter
```

Example 6-2: You want job2 to start *only if* job1 ends with no errors:

```
qsub job1
16397.jupiter
qsub -W depend=afterok:16397 job2
16396.jupiter
```

Example 6-3: job1 should run before job2 and job3. To use the beforeany dependency, you must use the on dependency:

```
qsub -W depend=on:2 job1
16397.jupiter
qsub -W depend=beforeany:16397 job2
16398.jupiter
qsub -W depend=beforeany:16397 job3
16399.jupiter
```

## 6.2.3 Job Array Dependencies

Job dependencies are supported:

- Between jobs and jobs
- Between job arrays and job arrays
- Between job arrays and jobs
- Between jobs and job arrays

Job dependencies are not supported for subjobs or ranges of subjobs.

---

## 6.2.4 Caveats and Advice for Job Dependencies

### 6.2.4.1 Correct Exit Status Required

Under Linux, make sure that job exit status is captured correctly; see [section 6.1, “Using Job Exit Status”, on page 107](#).

### 6.2.4.2 Permission Required for Dependencies

To use the `before` types, you must have permission to alter the jobs in *arg list*. Otherwise, the dependency is rejected and the new job is aborted.

### 6.2.4.3 Warning About Job History

Enabling job history changes the behavior of dependent jobs. If a job *j1* depends on a finished job *j2* for which PBS is maintaining history, PBS releases *j1*'s dependency, and takes appropriate action. If job *j1* depends on a finished job *j3* that has been purged from job history, *j1* is rejected just as in previous versions of PBS where the job was no longer in the system.

### 6.2.4.4 Error Reporting

PBS checks for errors in the existence, state, or condition of the job after accepting the job. If there is an error, PBS sends you mail about the error and deletes the job.

## 6.3 Adjusting Job Running Time

This feature was added in PBS Professional 12.0.

### 6.3.1 Shrink-to-fit Jobs

PBS allows you to submit a job whose running time can be adjusted to fit into an available scheduling slot. The job's minimum and maximum running time are specified in the `min_walltime` and `max_walltime` resources. PBS chooses the actual `walltime`. Any job that requests `min_walltime` is a **shrink-to-fit** job.

#### 6.3.1.1 Requirements for a Shrink-to-fit Job

A job must have a value for `min_walltime` to be a shrink-to-fit job. Shrink-to-fit jobs are not required to request `max_walltime`, but it is an error to request `max_walltime` and not `min_walltime`.

Jobs that do not have values for `min_walltime` are not shrink-to-fit jobs, and you can specify their `walltime`.

#### 6.3.1.2 Comparison Between Shrink-to-fit and Non-shrink-to-fit Jobs

The only difference between a shrink-to-fit and a non-shrink-to-fit job is how the job's `walltime` is treated. PBS sets the `walltime` when it runs the job. Any `walltime` value that exists before the job runs is ignored.

### 6.3.2 Using Shrink-to-fit Jobs

If you have jobs that can run for less than the expected time needed and still make useful progress, you can make them shrink-to-fit jobs in order to maximize utilization.

You can use shrink-to-fit jobs for the following:

- Jobs that are internally checkpointed. This includes jobs which are part of a larger effort, where a job does as much work as it can before it is killed, and the next job in that effort takes up where the previous job left off.
- Jobs using periodic PBS checkpointing
- Jobs whose real running time might be much less than the expected time
- When you have dedicated time for system maintenance, and you want to take advantage of time slots right up until shutdown, you can run speculative shrink-to-fit jobs if you can risk having a job killed before it finishes. Similarly, speculative jobs can take advantage of the time just before a reservation starts
- Any job where you do not mind running the job as a speculative attempt to finish some work

### 6.3.3 Running Time of a Shrink-to-fit Job

#### 6.3.3.1 Setting Running Time Range for Shrink-to-fit Jobs

It is only required that the job request `min_walltime` to be a shrink-to-fit job. Requesting `max_walltime` without requesting `min_walltime` is an error.

You can set the job's running time range by requesting `min_walltime` and `max_walltime`, for example:

```
qsub -l min_walltime=<min walltime>, max_walltime=<max walltime> <job script>
```

#### 6.3.3.2 Setting walltime for Shrink-to-fit Jobs

For a shrink-to-fit job, PBS sets the `walltime` resource based on the values of `min_walltime` and `max_walltime`, regardless of whether `walltime` is specified for the job.

PBS examines each shrink-to-fit job when it gets to it, and looks for a time slot whose length is between the job's `min_walltime` and `max_walltime`. If the job can fit somewhere, PBS sets the job's `walltime` to a duration that fits the time slot, and runs the job. The chosen value for `walltime` is visible in the job's `Resource_List.walltime` attribute. Any existing `walltime` value, regardless of where it comes from, e.g. previous execution, is reset to the new calculated running time.

If a shrink-to-fit job is run more than once, PBS recalculates the job's running time to fit an available time slot that is between `min_walltime` and `max_walltime`, and resets the job's `walltime`, each time the job is run.

For a multi-vnode job, PBS chooses a `walltime` that works for all of the chunks required by the job, and places job chunks according to the placement specification.

### 6.3.4 Modifying Shrink-to-fit and Non-shrink-to-fit Jobs

#### 6.3.4.1 Modifying min\_walltime and max\_walltime

You can change `min_walltime` and/or `max_walltime` for a shrink-to-fit job by using the `qalter` command. Any changes take effect after the current scheduling cycle. Changes affect only queued jobs; running jobs are unaffected unless they are rerun.

##### 6.3.4.1.i Making Non-shrink-to-fit Jobs into Shrink-to-fit Jobs

You can convert a normal non-shrink-to-fit job into a shrink-to-fit job using the `qalter` command to set values for `min_walltime` and `max_walltime`.

Any changes take effect after the current scheduling cycle. Changes affect only queued jobs; running jobs are unaffected unless they are rerun.

### 6.3.4.1.ii Making Shrink-to-fit Jobs into Non-shrink-to-fit Jobs

To make a shrink-to-fit job into a normal, non-shrink-to-fit job, use the `qalter` command to do the following:

- Set the job's `walltime` to the value for `max_walltime`
- Unset `min_walltime`
- Unset `max_walltime`

## 6.3.5 Viewing Running Time for a Job

### 6.3.5.1 Viewing `min_walltime` and `max_walltime`

You can use `qstat -f` to view the values of `min_walltime` and `max_walltime`. For example:

```
% qsub -lmin_walltime=01:00:15, max_walltime=03:30:00 job.sh
<job-id>
% qstat -f <job-id>
...
Resource_List.min_walltime=01:00:15
Resource_List.max_walltime=03:30:00
```

You can use `tracejob` to display `max_walltime` and `min_walltime` as part of the job's resource list. For example:

```
12/16/2011 14:28:55 A user=pbsadmin group=Users project=_pbs_project_default
...
Resource_List.max_walltime=10:00:00
Resource_List.min_walltime=00:00:10
```

### 6.3.5.2 Viewing `walltime` for a Shrink-to-fit Job

PBS sets a job's `walltime` only when the job runs. While the job is running, you can see its `walltime` via `qstat -f`. While the job is not running, you cannot see its real `walltime`; it may have a value set for `walltime`, but this value is ignored.

You can see the `walltime` value for a finished shrink-to-fit job if you are preserving job history. See [section 13.15, "Managing Job History", on page 519](#).

## 6.3.6 Lifecycle of a Shrink-to-fit Job

### 6.3.6.1 Execution of Shrink-to-fit Jobs

Shrink-to-fit jobs are started just like non-shrink-to-fit jobs.

### 6.3.6.2 Termination of Shrink-to-fit Jobs

When a shrink-to-fit job exceeds the `walltime` PBS has set for it, it is killed by PBS exactly as a non-shrink-to-fit job is killed when it exceeds its `walltime`.

### 6.3.7 The min\_walltime and max\_walltime Resources

#### max\_walltime

Maximum **walltime** allowed for a shrink-to-fit job. Job's actual **walltime** is between **max\_walltime** and **min\_walltime**. PBS sets **walltime** for a shrink-to-fit job. If this resource is specified, **min\_walltime** must also be specified. Must be greater than or equal to **min\_walltime**. Cannot be used for **resources\_min** or **resources\_max**. Cannot be set on job arrays or reservations. If not specified, PBS uses 5 years as the maximum time slot. Can be requested only outside of a select statement. Non-consumable. Default: None. Type: duration. Python type: pbs.duration

#### min\_walltime

Minimum **walltime** allowed for a shrink-to-fit job. When this resource is specified, job is a shrink-to-fit job. If this attribute is set, PBS sets the job's **walltime**. Job's actual **walltime** is between **max\_walltime** and **min\_walltime**. Must be less than or equal to **max\_walltime**. Cannot be used for **resources\_min** or **resources\_max**. Cannot be set on job arrays or reservations. Can be requested only outside of a select statement. Non-consumable. Default: None. Type: duration. Python type: pbs.duration

### 6.3.8 Caveats and Restrictions for Shrink-to-fit Jobs

It is erroneous to specify **max\_walltime** for a job without specifying **min\_walltime**. If attempted via **qsub** or **qalter**, the following error is printed:

```
'Can not have "max_walltime" without "min_walltime"'
```

It is erroneous to specify a **min\_walltime** that is greater than **max\_walltime**. If attempted via **qsub** or **qalter**, the following error is printed:

```
'"min_walltime" can not be greater than "max_walltime"'
```

Job arrays cannot be shrink-to-fit. You cannot have a shrink-to-fit job array. It is erroneous to specify a **min\_walltime** or **max\_walltime** for a job array. If attempted via **qsub** or **qalter**, the following error is printed:

```
'"min_walltime" and "max_walltime" are not valid resources for a job array'
```

Reservations cannot be shrink-to-fit. You cannot have a shrink-to-fit reservation. It is erroneous to set **min\_walltime** or **max\_walltime** for a reservation. If attempted via **pbs\_rsub**, the following error is printed:

```
'"min_walltime" and "max_walltime" are not valid resources for reservation.'
```

It is erroneous to set **resources\_max** or **resources\_min** for **min\_walltime** and **max\_walltime**. If attempted, the following error message is displayed, whichever is appropriate:

```
"Resource limits can not be set for min_walltime"
```

```
"Resource limits can not be set for max_walltime"
```

## 6.4 Using Checkpointing

### 6.4.1 Prerequisites for Checkpointing

A job is checkpointable if it has not been marked as non-checkpointable and any of the following is true:

- Its application supports checkpointing and your administrator has set up checkpoint scripts
- There is a third-party checkpointing application available
- The OS supports checkpointing

## 6.4.2 Minimum Checkpoint Interval

The execution queue in which the job resides controls the minimum interval at which a job can be checkpointed. The interval is specified in CPU minutes or walltime minutes. The same value is used for both, so for example if the minimum interval is specified as 12, then a job using the queue's interval for CPU time is checkpointed every 12 minutes of CPU time, and a job using the queue's interval for walltime is checkpointed every 12 minutes of walltime.

## 6.4.3 Syntax for Specifying Checkpoint Interval

Use the “`-c checkpoint-spec`” option to `qsub` to specify the interval, in CPU minutes, or in walltime minutes, at which the job will be checkpointed.

The *checkpoint-spec* argument is specified as:

**C**

Job is checkpointed at the interval, measured in CPU time, set on the execution queue in which the job resides.

**C=<minutes of CPU time>**

Job is checkpointed at intervals of the specified number of minutes of CPU time used by the job. This value must be greater than zero. If the interval specified is less than that set on the execution queue in which the job resides, the queue's interval is used.

Format: *Integer*

**W**

Job is checkpointed at the interval, measured in walltime, set on the execution queue in which the job resides.

**w=<minutes of walltime>**

Checkpointing is to be performed at intervals of the specified number of minutes of walltime used by the job. This value must be greater than zero. If the interval specified is less than that set on the execution queue in which the job resides, the queue's interval is used.

Format: *Integer*

**n**

Job is not checkpointed.

**s**

Job is checkpointed only when the PBS server is shut down.

**u**

Checkpointing is unspecified, and defaults to the same behavior as “s”.

The Checkpoint job attribute controls the job's checkpoint interval. You can set it using the `qsub` command line or a PBS directive:

Use `qsub` to specify that the job should use the execution queue's checkpoint interval:

```
qsub -c c my_job
```

Use a directive to checkpoint the job every 10 minutes of CPU time:

```
#PBS -c c=10
```

## 6.4.4 Using Checkpointing for Preempting or Holding Jobs

Your site may need to preempt jobs while they are running, or you may want to be able to place a hold your job while it runs. To allow either of these, make your job checkpointable. This means that you should not mark it as non-checkpointable (do not use `qsub -c n`), your application must be checkpointable or there is a third-party checkpointing application, and your administrator must supply a checkpoint script to be run by the MoM where the job runs.

You can use application-level checkpointing when your job is preempted or you place a hold on it to save the partial results. When your checkpointed job is restarted, your job script can find that the job was checkpointed, and can start from the checkpoint file instead of starting from scratch.

If you try to hold a running job that is not checkpointable (either it is marked as non-checkpointable or the script is missing or returns failure), the job continues to run with its `Hold_Types` attribute set to *h*. See [section 6.5, “Holding and Releasing Jobs”, on page 115](#).

## 6.4.5 Caveats and Restrictions for Checkpointing

- Checkpointing is not supported for job arrays.
- If you do not specify `qsub -c checkpoint-spec`, it is unspecified, and defaults to the same as “s”.
- PBS limits the number of times it tries to run a job to 21, and tracks this count in the job’s `run_count` attribute. If your job is checkpointed and requeued enough times, it will be held.

## 6.5 Holding and Releasing Jobs

You can place a hold on your job to do the following:

- A queued job remains queued until you release the hold; see [section 6.5.3, “Holding a Job Before Execution”, on page 116](#)
- A running job stops running but can resume where it left off; see [section 6.5.4.1, “Checkpointing and Requeueing the Job”, on page 116](#)
- A running job continues to run but is held if it is requeued; see [section 6.5.4.2, “Setting Hold Type for a Running Job”, on page 116](#)

You hold a job using the `qhold` command; see [“qhold” on page 147 of the PBS Professional Reference Guide](#).

You can release a held queued job to make it eligible to be scheduled to run, and you can release a hold on a running job. You release a hold on your job using the `qrls` command; see [“qrls” on page 180 of the PBS Professional Reference Guide](#).

The `qhold` command uses the following syntax:

```
qhold [-h <hold list>] <job ID> [<job ID> ...]
```

The `qrls` command uses the following syntax:

```
qrls [-h <hold list>] <job ID> [<job ID> ...]
```

For a job array the *job ID* must be enclosed in double quotes.

### 6.5.1 Types of Holds

The *hold list* specifies the types of holds to be placed on the job. The *hold list* argument is a string consisting of one or more of the letters *u*, *p*, *o*, or *s* in any combination, or the letter *n*. The following table shows the hold type associated with each letter:

**Table 6-1: Hold Types**

| Hold Type | Meaning      | Who Can Set or Release                                   |
|-----------|--------------|----------------------------------------------------------|
| <i>u</i>  | <i>User</i>  | <i>Job owner, Operator, Manager, administrator, root</i> |
| <i>o</i>  | <i>Other</i> | <i>Operator, Manager, administrator, root</i>            |

Table 6-1: Hold Types

| Hold Type | Meaning             | Who Can Set or Release                                   |
|-----------|---------------------|----------------------------------------------------------|
| <i>s</i>  | <i>System</i>       | <i>Manager, administrator, root, PBS (dependency)</i>    |
| <i>n</i>  | <i>No hold</i>      | <i>Job owner, Operator, Manager, administrator, root</i> |
| <i>p</i>  | <i>Bad password</i> | <i>Administrator, root</i>                               |

If no `-h` option is specified, PBS applies a *user* hold to the jobs listed in the *job ID* list.

If a job in the *job ID* list is in the queued, held, or waiting states, the only change is that the hold type is added to the job's other holds. If the job is queued or waiting in an execution queue, the job is also put in the held state.

## 6.5.2 Requirements for Holding or Releasing a Job

The user executing the `qhold` or `qrls` command must have the necessary privilege to apply a hold or release a hold. The same rules apply for releasing a hold and for setting a hold.

## 6.5.3 Holding a Job Before Execution

Normally, PBS runs your job as soon as an appropriate slot opens up. However, you can tell PBS that the job is ineligible to run and should remain queued. Use the “`-h`” option to `qsub` to apply a *user hold* to the job when you submit it. PBS accepts the job and places it in the *held* state. The job remains held and ineligible to run until the hold is released.

The `Hold_Types` job attribute controls the job's holding behavior; set it via `qsub` or a directive:

```
qsub -h my_job
#PBS -h
```

## 6.5.4 Holding a Job During Execution

### 6.5.4.1 Checkpointing and Requeueing the Job

If your job is checkpointable, you can stop its execution by holding it. In this case the following happens:

- The job is checkpointed
- The resources assigned to the job are released
- The job is put back in the execution queue in the Held state

See [section 6.4.1, “Prerequisites for Checkpointing”, on page 113](#).

To hold your job, use the `qhold` command:

```
qsub -h my_job
```

### 6.5.4.2 Setting Hold Type for a Running Job

If your job is not checkpointable, `qhold` merely sets the job's `Hold_Types` attribute. This has no effect unless the job is requeued with the `qrerun` command. In that case the job remains queued and ineligible to run until you release the hold.

## 6.5.5 Releasing a Job

You can release one or more holds on a job by using the `qrls` command.

The `qrls` command uses the following syntax:

```
qrls [-h <hold list>] <job ID> ...
```

For job arrays, the *job ID* must be enclosed in double quotes.

If you try to release a hold on a job which is not held, the `qrls` command is ignored. If you use the `qrls` command to release a hold on a job that had been previously running and was checkpointed, the hold is released and the job is returned to the queued (Q) state, and the job becomes eligible to be scheduled to run when resources come available.

The `qrls` command does not run the job; it simply releases the hold and makes the job eligible to be run the next time the scheduler selects it.

## 6.5.6 Caveats and Restrictions for Holding and Releasing Jobs

- The `qhold` command can be used on job arrays, but not on subjobs or ranges of subjobs. On job arrays, the `qhold` command can be applied only in the 'Q', 'B' or 'W' states. This will put the job array in the 'H', held, state. If any subjobs are running, they will run to completion. Job arrays cannot be moved in the 'H' state if any subjobs are running.
- Checkpointing is not supported for job arrays. Even on systems that support checkpointing, no subjobs will be checkpointed; they will run to completion.
- To hold a running job and stop its execution, the job must be checkpointable. See [section 6.4.1, “Prerequisites for Checkpointing”, on page 113](#).
- The `qrls` command can only be used with job array objects, not with subjobs or ranges. The job array will be returned to its pre-hold state, which can be either 'Q', 'B', or 'W'.
- The `qhold` command can only be used with job array objects, not with subjobs or ranges. A hold can be applied to a job array only from the 'Q', 'B' or 'W' states. This will put the job array in the 'H', held, state. If any subjobs are running, they will run to completion. No queued subjobs will be started while in the 'H' state.
- PBS limits the number of times it tries to run a job to 21, and tracks this count in the job's `run_count` attribute. If your job is checkpointed and requeued enough times, it will be held.

## 6.5.7 Why is Your Job Held?

Your job may be held for any of the following reasons:

- Provisioning fails due to invalid provisioning request or to internal system error ("s")
- After provisioning, the AOE reported by the vnode does not match the AOE requested by the job ("s")
- The job was held by a PBS Manager or Operator ("o")
- The job was checkpointed and requeued ("s")
- Your job depends on a finished job for which PBS is maintaining history ("s")
- The job's password is invalid ("p")
- The job's `run_count` attribute has a value greater than 20.

## 6.5.8 Examples of Holding and Releasing Jobs

The following examples illustrate how to use both the `qhold` and `qrls` commands. Notice that the state (“S”) column shows how the state of the job changes with the use of these two commands.

```
qstat -a 54
```

| Job ID   | User  | Queue | Jobname | Sess | NDS | TSK | Mem | Time | Req'd | Elap |
|----------|-------|-------|---------|------|-----|-----|-----|------|-------|------|
|          |       |       |         |      |     |     |     |      | S     | Time |
| 54.south | barry | workq | engine  | --   | --  | 1   | --  | 0:20 | Q     | --   |

```
qhold 54
```

```
qstat -a 54
```

| Job ID   | User  | Queue | Jobname | Sess | NDS | TSK | Mem | Time | Req'd | Elap |
|----------|-------|-------|---------|------|-----|-----|-----|------|-------|------|
|          |       |       |         |      |     |     |     |      | S     | Time |
| 54.south | barry | workq | engine  | --   | --  | 1   | --  | 0:20 | H     | --   |

```
qrls -h u 54
```

```
qstat -a 54
```

| Job ID   | User  | Queue | Jobname | Sess | NDS | TSK | Mem | Time | Req'd | Elap |
|----------|-------|-------|---------|------|-----|-----|-----|------|-------|------|
|          |       |       |         |      |     |     |     |      | S     | Time |
| 54.south | barry | workq | engine  | --   | --  | 1   | --  | 0:20 | Q     | --   |

## 6.6 Allowing Your Job to be Re-run

You can specify whether or not your job is eligible to be re-run if for some reason the job is terminated before it finishes. Use the “-r” option to `qsub` to specify whether the job is rerunnable. The argument to this option is “y”, meaning that the job can be re-run, or “n”, meaning that it cannot. If you do not specify whether or not your job is rerunnable, it is rerunnable.

If running your job more than once would cause a problem, mark your job as non-rerunnable. Otherwise, leave it as rerunnable. The purpose of marking a job as non-rerunnable is to prevent it from starting more than once.

If a job that is marked non-rerunnable has an error during startup, before it begins execution, that job is queued for another attempt.

The `Rerunnable` job attribute controls whether the job is rerunnable; you can set it via `qsub` or a PBS directive:

```
qsub -r n my_job
#PBS -r n
```

The following table lists the circumstances where the job's Rerunable attribute makes a difference or does not:

**Table 6-2: When does Rerunable Attribute Matter?**

| Circumstance                                                                       | Rerunable         | Not Rerunable      |
|------------------------------------------------------------------------------------|-------------------|--------------------|
| Job fails upon startup, before running                                             | Job is queued     | Job is queued      |
| Job is running on multiple hosts, and one host goes down                           | Job is queued     | Job is deleted     |
| Job is scheduled to run on multiple hosts, and did not start on at least one host  | Job is queued     | Job is queued      |
| Server is shut down with a delay                                                   | Job is queued     | Job finishes       |
| Server is shut down immediately                                                    | Job is queued     | Job is deleted     |
| Job requests provisioning and provisioning script fails                            | Job is queued     | Job is queued      |
| Job is running on multiple hosts and one host becomes busy due to console activity | Job is queued     | Job is deleted     |
| Higher-priority job needs resources                                                | Job may be queued | Job may be deleted |

### 6.6.1 Caveats and Restrictions for Marking Jobs as Rerunable

- Interactive jobs are not rerunable.
- Job arrays are required to be rerunable. PBS will not accept a job array that is marked as not rerunable. You can submit a job array without specifying whether it is rerunable, and PBS will automatically mark it as rerunable.
- Mark your job as not rerunable only if running it more than once would cause a problem. If your job is marked as not rerunable, and a higher-priority job needs resources, your job could be deleted.

## 6.7 Controlling Number of Times Job is Re-run

PBS has a built-in limit of 21 on the number of times it will try to run your job. The number of attempts is tracked in the job's `run_count` attribute. By default, the value of `run_count` is zero at job submission. The job is held when the value of `run_count` goes above 20.

You can reduce the number of times PBS attempts to run your job. You can specify a non-negative value for `run_count` at job submission, and you can use `qalter` to raise the value of `run_count` while the job is running. You cannot give a job more retries than the limit, and you cannot lower the value of `run_count` while the job is running.

### 6.7.1 Caveats for Raising Value of `run_count` Attribute

If your job is checkpointed and queued enough times, it will be held.

## 6.8 Deferring Execution

Normally, PBS runs your job as soon as an appropriate slot opens up. Instead, you can specify a time after which the job is eligible to run. The job is in the wait (W) state from the time it is submitted until the time it is eligible for execution.

## 6.8.1 Syntax for Deferring Execution

Use the “-a <datetime>” option to `qsub` to specify the time after which the job is eligible for execution. The *datetime* argument is in the form:

```
[[[CC]YY]MM]DD]hhmm[.SS]
```

where

*CC* is the first two digits of the year (the century): optional

*YY* is the second two digits of the year: optional

*MM* is the two digits for the month: optional

*DD* is the day of the month: optional

*hh* is the hour

*mm* is the minute

*SS* is the seconds: optional

If the day *DD* is in the future, and the month *MM* is not specified, the month defaults to the current month. If the day *DD* is in the past, and the month *MM* is not specified, the month is set to next month. For example, if today is the 10th, and you specify the 12th but no month, your job is eligible to run two days from today, on the 12th.

Similarly, if the time *hhmm* is in the future, and the day *DD* is not specified, the day defaults to the current day. If the time *hhmm* is in the past, and the day *DD* is not specified, the day is set to tomorrow. For example, if you submit a job at 11:15am with a time of “1110”, the job will be eligible to run at 11:10am tomorrow.

The job’s Execution \_Time attribute controls deferred execution. You can set it using either of the following:

```
qsub -a 0700 my_job
#PBS -a 10220700
```

## 6.9 Setting Priority for Your Job

PBS includes a place in each job where you can specify the job’s priority. Your administrator may or may not choose to use this priority value when scheduling jobs. Use the “-p <priority>” to specify the priority of the job. The *priority* argument must be an integer between -1024 (lowest priority) and +1023 (highest priority) inclusive. The default is unset, which is equivalent to zero.

The Priority job attribute contains the value you specify. Set it via `qsub` or a directive:

```
qsub -p 120 my_job
#PBS -p -300
```

If you need an absolute ordering of your own jobs, see [section 6.2, “Using Job Dependencies”, on page 107](#).

## 6.10 Making `qsub` Wait Until Job Ends

Normally, when you submit a job, the `qsub` command exits after returning the ID of the new job. You can use the “-w block=true” option to `qsub` to specify that you want `qsub` to “block”, meaning wait for the job to complete and report the exit value of the job.

If your job is successfully submitted, `qsub` blocks until the job terminates or an error occurs. If job submission fails, no special processing takes place.

If the job runs to completion, `qsub` exits with the exit status of the job. For job arrays, blocking `qsub` waits until the entire job array is complete, then returns the exit status of the job array.

The `block` job attribute controls blocking. Set it either via `qsub` or a PBS directive:

```
qsub -W block=true
#PBS block=true
```

## 6.10.1 Signal Handling and Error Processing for Blocking Jobs

Signals `SIGQUIT` and `SIGKILL` are not trapped, and immediately terminate the `qsub` process, leaving the associated job either running or queued.

If `qsub` receives one of the signals `SIGHUP`, `SIGINT`, or `SIGTERM`, it prints a message and then exits with an exit status of 2.

If the job is deleted before running to completion, or an internal PBS error occurs, `qsub` prints an error message describing the situation to this error stream and `qsub` exits with an exit status of 3.

## 6.10.2 Caveats for Blocking Jobs

- If you submit a job that is both blocking and interactive, the job's exit status is not returned at the end of the job.
- PBS returns the exit status of a blocking job before staging finishes for the job. To see whether the job is still staging, use `qstat -f`, and look at the job's `substate` attribute. This attribute has value `51` when files are staging out.

## 6.11 Running Your Job Interactively

PBS provides a special kind of batch job called an *interactive-batch job* or *interactive job*. An interactive job is treated just like a regular batch job in that it is queued up, and has to wait for resources to become available before it can run. However, once it starts, your terminal input and output are connected to the job similarly to a login session. It appears that you are logged into one of the available execution machines, and the resources requested by the job are reserved for that job. This is useful for debugging applications or for computational steering.

You can use GUI applications in interactive jobs on remote hosts. The PBS interface is slightly different on Linux and Windows. For Linux, see [section 6.11.9, “Receiving X Output from Interactive Linux Jobs”, on page 124](#). For Windows, see [section 6.11.10, “Submitting Interactive GUI Jobs on Windows”, on page 125](#).

Interactive jobs can use provisioning.

### 6.11.1 Input and Output for Interactive Jobs

An interactive job comes complete with a pseudotty suitable for running commands that set terminal characteristics. Once the interactive job has started execution, input to and output from the job pass through `qsub`. You provide all input to your interactive job through the terminal session in which the job runs.

For interactive jobs, you can specify PBS directives in a job script. You cannot provide commands to the job by using a job script. For interactive jobs, PBS ignores executable commands in job scripts.

---

## 6.11.2 Running Your Interactive Job

To run your job interactively, you can do either of the following:

- Use `qsub -I` at the command line
- Use `#PBS interactive=true` (**deprecated**) in a PBS directive

When your interactive job is running, you can run commands, executables, shell scripts, DOS commands, etc. These commands behave normally; for example, if the path to a command is not in your `PATH` environment variable, you must provide the full path.

## 6.11.3 Lifecycle of an Interactive Job

1. You start the interactive job using `qsub #PBS interactive=true` (**deprecated**) or `-I`
2. If there is a script, PBS processes any directives in the script
3. The scheduler runs the job
4. Output is connected to the submission window
5. You run commands, executables, shell scripts, etc. interactively
6. The job is terminated

### 6.11.3.1 Terminating Interactive Jobs

When you run an interactive job, the `qsub` command does not terminate when the job is submitted. `qsub` remains running until one of the following:

- You `qdel` the job
- Someone else deletes the job
- You exit the shell
- The job is aborted
- You interrupt `qsub` with a `SIGINT` (the control-C key) before the scheduler starts the job.

Once the scheduler starts the job, `SIGINT` is ignored.

Under Linux, if you interrupt `qsub` before the job starts, `qsub` queries whether you want it to exit. If you respond “yes”, `qsub` exits and the job is aborted. Under Windows, if you interrupt the job before it starts, the job is deleted, and the following messages are printed:

```
qsub: wait for job <job ID> interrupted by signal 2
<job ID> is being deleted
```

## 6.11.4 Interactive Jobs and Exit Codes

Under Windows, if you specify an exit code when you exit the interactive session, via “exit <exit code>”, that exit code is used as the job’s exit code. This exit code is visible in the output of the `tracejob` command.

Under Linux, you cannot provide an exit code for the interactive session.

## 6.11.5 Tracking Progress for Interactive Jobs

After you have submitted an interactive job, PBS prints the following message to the window where you submitted the job:

```
qsub: waiting for job <job ID> to start
```

When the job is started by the scheduler, PBS prints the following message to the submission window:

```
qsub: job <job ID> ready
```

When the interactive job finishes, PBS prints the following message to the submission window:

```
qsub: job <job ID> completed
```

## 6.11.6 Special Sequences for Interactive Jobs

Keyboard-generated interrupts are passed to the job. Lines entered that begin with the tilde (~) character and contain special sequences are interpreted by `qsub` itself. The recognized special sequences are:

~.

`qsub` terminates execution. The batch job is also terminated.

~susp

Suspends the `qsub` program. “*susp*” is the suspend character, usually CTRL-Z.

~asusp

Suspends the input half of `qsub` (terminal to job), but allows output to continue to be displayed. “*asusp*” is the auxiliary suspend character, usually control-Y.

## 6.11.7 Caveats and Restrictions for Interactive Jobs

- Make sure that your login file does not run processes in the background. See [section 1.4.2.5, “Avoid Background Processes Inside Jobs”, on page 6](#).
- You cannot run an array job interactively.
- Interactive jobs are not rerunnable.
- An interactive job on a Cray must run on a login node. See [section 11.4.6, “Specify Host for Interactive Jobs on Cray XC”, on page 193](#).
- You cannot use the CLS command in an interactive job. It will not clear the screen.
- After the scheduler has started the interactive job, SIGINT (Ctrl-C) is ignored.
- Under Linux, you cannot provide an exit code for the interactive session.
- When an interactive job finishes, staged files and *stdout* and/or *stderr* may not have been copied back yet.
- The submission host must accept incoming ephemeral ports

## 6.11.8 Errors and Logging

- If PBS cannot open a remote interactive shell to run an interactive job, PBS prints the following error message:  
"qsub: failed to run remote interactive shell"
- If IPC\$ on the remote host cannot be connected, PBS prints the following message:  
"Couldn't connect to host <hostname>"
- If PBS is successful in connecting to the IPC\$ at the execution host, but fails to execute the remote shell, PBS prints the following error message:  
"Couldn't execute remote shell at host <hostname>"

## 6.11.9 Receiving X Output from Interactive Linux Jobs

Under Linux, you can receive X output from an interactive job via the `qsub -X` option.

### 6.11.9.1 How to Receive X Output Under Linux

To receive X output, use `qsub -X -I`. For example:

```
qsub -I -X <return>
xterm <return>
```

Control is returned here when your X process terminates. You can background the process here, if you want to.

#### 6.11.9.1.i Receiving X Output on Non-submission Host

You can view your X output on a host that is not the job submission host. For example, you submit a job from SubHost, and want to see the output on ViewHost. If you want to receive X output on a host that is not the submission host, for example ViewHost, do the following:

- Run an X server on ViewHost
- On ViewHost, log into SubHost using `ssh -X`
- In window logged into SubHost, run `qsub -I -X`

### 6.11.9.2 Requirements for Receiving X Output

- You must be running Linux.
- The job must be interactive: you must also specify `-I`.
- An X server must be running on the system where you want to see the X output.
- The `DISPLAY` variable in the job's submission environment must be set to the display where the X output is desired.
- Your administrator must configure MoM's `PATH` to include the `xauth` utility.

### 6.11.9.3 Viewing X Output Job Attributes

Each job has two read-only attributes containing X forwarding information. These are the following:

`forward_x11_cookie`

This attribute contains the X authorization cookie.

`forward_x11_port`

This attribute contains the number of the port being listened to by the port forwarder on the submission host.

You can view these attributes using `qstat -f <job ID>`.

### 6.11.9.4 Caveats and Advice for Receiving X Output

- This option is not available under Windows.
- If you use the `qsub -v` option, PBS will handle the `DISPLAY` variable correctly.
- If you use the `qsub -v DISPLAY` option, you will get an error.
- At most 25 concurrent X applications can run using the same job session.
- If you experience a problem with X when using `qsub -X -I`, use the following to create the correct `~/.Xauthority` file for `qsub` to use when establishing the X session:  

```
ssh -X <hostname> server <-> <exec host(s)>
```

### 6.11.9.5 X Forwarding Errors

- If the `DISPLAY` environment variable is pointing to a display number that is correctly formatted but incorrect, submitting an interactive X forwarding job results in the following error message:  
`"cannot read data from 'xauth list <display number>', errno=<errno>"`
- If the `DISPLAY` environment variable is pointing to an incorrectly formatted value, submitting an interactive X forwarding job results in the following error message:  
`"qsub: Failed to get xauth data (check $DISPLAY variable)"`
- If the X authority utility (`xauth`) is not found on the submission host, the following error message is displayed:  
`"execution of xauth failed: sh: xauth: command not found"`
- When the execution of the `xauth` utility results in an error, the error message displayed by the `xauth` utility is preceded by the following:  
`"execution of xauth failed: "`
- When the `qsub -X` option is used without `-I`, the following error message is displayed:  
`"qsub: X11 forwarding possible only for Interactive Jobs"`

### 6.11.10 Submitting Interactive GUI Jobs on Windows

You can run an interactive job that uses a GUI application. If the job executes on a host other than the one from which you submit the job, PBS uses a remote viewer or interactive shell to connect the GUI application to the remote host. Under Windows, PBS supports any GUI application, including Remote Viewer and X. If your job requires a GUI application or interactive shell, you must run it as an interactive job.

To run an interactive PBS job that launches a GUI application:

```
qsub -I -G -- <GUI application>
```

When the same host is used for submission and execution, the application is launched on the local console. No remote viewer client is launched.

When the submission and execution hosts are different, the GUI application is launched in the remote session using the specified remote viewer. The remote viewer client is launched.

To run X under Windows, do not use the `-X` option. This option is not available under Windows. Use `-G`.

To launch an interactive shell in a PBS job:

```
qsub -I -G
```

When the submission and execution host are the same, the interactive shell is launched on the local console. No remote viewer client is launched.

When the submission and execution hosts are different, the interactive shell is launched, and any GUI application launched through this shell is visible in the remote session using the configured remote viewer. The remote viewer client is launched.

Your interactive GUI job is finished or no longer running under the following circumstances:

- When the GUI application launched via `qsub -I -G <GUI application>` is closed
- When the interactive shell launched via `qsub -I -G` exits
- When the remote viewer is terminated, closed, or logged off, all applications started by the remote viewer are closed.
- When a GUI job is deleted via `qdel`, all the applications and tasks associated with the job are killed

See [“-G \[<path to GUI application or script>\]” on page 220 of the PBS Professional Reference Guide.](#)

## 6.12 Using Environment Variables

PBS provides your job with environment variables where the job runs. PBS takes some from your submission environment, and creates others. You can create environment variables for your job. The environment variables created by PBS begin with “*PBS\_*”. The environment variables that PBS takes from your submission (originating) environment begin with “*PBS\_O\_*”.

For example, here are a few of the environment variables that accompany a job, with typical values:

```
PBS_O_HOME=/u/user1
PBS_O_LOGNAME=user1
PBS_O_PATH=/usr/bin:/usr/local/bin:/bin
PBS_O_SHELL=/bin/tcsh
PBS_O_HOST=host1
PBS_O_WORKDIR=/u/user1
PBS_JOBID=16386.server1
```

For a complete list of PBS environment variables, see [“PBS Environment Variables” on page 399 of the PBS Professional Reference Guide.](#)

### 6.12.1 Exporting All Environment Variables

The “`-V`” option declares that all environment variables in the `qsub` command’s environment are to be exported to the batch job.

```
qsub -V my_job
#PBS -V
```

### 6.12.2 Exporting Specific Environment Variables

The “`-v <variable list>`” option to `qsub` allows you to specify additional environment variables to be exported to the job. *variable list* names environment variables from the `qsub` command environment which are made available to the job when it executes. These variables and their values are passed to the job. These variables are added to those already automatically exported. Format: comma-separated list of strings in the form:

```
-v <variable>
or
-v <variable>=<value>
```

If a `<variable>=<value>` pair contains any commas, the value must be enclosed in single or double quotes, and the `<variable>=<value>` pair must be enclosed in the kind of quotes not used to enclose the value. For example:

```
qsub -v DISPLAY,myvariable=32 my_job
qsub -v "var1='A,B,C,D'" job.sh
qsub -v a=10, "var2='A,B'", c=20, HOME=/home/zzz job.sh
```

## 6.12.3 Caveat for Environment Variables and Shell Functions

Make sure that no exported shell function you want to forward has the same name as an environment variable. The shell function will not be visible in the environment.

## 6.12.4 Forwarding Exported Shell Functions

You can forward exported shell functions using either `qsub -V` or `qsub -v <function name>`. You can also put these functions in your `.profile` or `.login` on the execution host(s).

If you use `-v` or `-V`, make sure that there is no environment variable with the same name as any exported shell functions you want to forward; otherwise, the shell function will not be visible in the environment.

## 6.13 Specifying Which Jobs to Preempt

You can specify which groups of jobs your job is allowed to preempt in order to run. You can specify all the jobs in one or more queues, and all jobs that request particular resources, by listing them in the `preempt_targets` resource.

Syntax:

```
...-l preempt_targets="queue=<queue name>[,queue=<queue name>],
 Resource_List.<resource>=<value>[,Resource_List.<resource>=<value>]"
```

For example, to specify that your job can preempt jobs in the queue named QueueA and/or jobs that requested `arch=linux`:

```
...-l preempt_targets="queue=QueueA,Resource_List.arch=linux"
```

You can prevent a job from preempting any other job in the complex by setting its `preemption_targets` to the keyword “None” (case-insensitive).

Make the `preempt_targets` resource specification last or use another `-l` specification for subsequent resource specifications. Otherwise, subsequent resource specifications will look to PBS like additions to `preempt_targets`.

## 6.14 Releasing Unneeded Vnodes from Your Job

If you want to prevent unnecessary resource usage, you can release unneeded sister hosts or vnodes (not the primary execution host or its vnodes) from your job. You can use the `pbs_release_nodes` command or the `release_nodes_on_stageout` job attribute:

- You can use the `pbs_release_nodes` command either at the command line or in your job script to release sister hosts or vnodes when the command is issued. You can use this command to release specific vnodes that are not on the primary execution host, or all vnodes that are not on the primary execution host. You can also use it to release all hosts or vnodes except for what you specify, which can be either a count of hosts to keep, or a select specification describing the vnodes to keep. You cannot use the command to release vnodes on the primary execution host. See [“pbs\\_release\\_nodes” on page 92 of the PBS Professional Reference Guide](#).
- You can set the job’s `release_nodes_on_stageout` attribute to `True` so that PBS releases all of the job’s vnodes that are not on the primary execution host when stageout begins. You must set the job’s `stageout` attribute as well. See [“Job Attributes” on page 328 of the PBS Professional Reference Guide](#).

### 6.14.1 Caveats and Restrictions for Releasing Vnodes

- You must specify a stageout parameter in order to be able to release vnodes on stageout. If you do not specify stageout, `release_nodes_on_stageout` has no effect.
- You can release only vnodes that are not on the primary execution host. You cannot release vnodes on the primary execution host.
- The job must be running (in the *R* state).
- The `pbs_release_nodes` command is not supported on vnodes tied to Cray X\* series systems (vnodes whose `vntype` has the “cray\_” prefix).
- If cgroups support is enabled, and `pbs_release_nodes` is called to release some but not all the vnodes managed by a MoM, resources on those vnodes are released.
- If a vnode on a multi-vnode host is assigned exclusively to a job, and the vnode is released, the job will show that the vnode is released, but the vnode will still show as assigned to the job in `pbsnodes -av` until the other vnodes on that host have been released. If a vnode on a multi-vnode machine is not assigned exclusively to a job, and the vnode is released, it shows as released whether or not the other vnodes on that host are released.
- If you specify release of a vnode on which a job process is running, that process is terminated when the vnode is released.

### 6.14.2 What Happens When You Release Vnodes

After you release a job’s vnode:

- The job’s `$PBS_NODEFILE` no longer lists the released vnode
- The server continues to hold on to the job until receiving confirmation that the job has been cleaned up from the vnode
- The vnode reports to the primary execution host MoM its `resources_used*` values for the job as the final action. The released vnode no longer updates the `resources_used` values for the job since it’s no longer part of the job. But the primary execution host holds onto the data, and adds the data during final aggregation of `resources_used` values when job exits
- After every successful call to `pbs_release_nodes`, `qstat` shows updated values for the job’s `exec_host`, `exec_vnode`, and `Resource_List` attributes

When releasing vnodes, if all vnodes assigned to a job managed by the same MoM have been released, the job is completely removed from that MoM's host. This results in the following:

- The `execjob_epilogue` hook script (if it exists) runs
- Job processes are killed on that host
- Any job-specific specific files including job temporary directories are removed

If one or more, but not all, the vnodes from an execution host assigned to a job are released, the job is not removed from that host yet. If those released vnodes have been configured to be shared, they can be reassigned to other jobs.

## 6.14.3 Examples of Releasing Unneeded Vnodes From Job

Example 6-4: Submit a job that will release its non-primary-execution-host vnodes on stageout:

```
% qsub -W stageout=my_stageout@executionhost2:my_stageout.out -W release_nodes_on_stageout=true
job.scr
```

Example 6-5: Release particular vnodes from a job:

```
Syntax: pbs_release_nodes [-j <job ID>] <vnode name> [<vnode name>] ...]

% qsub job.scr
241.myserverhost
% qstat 241 | grep "exec|Resource_List|select"
exec_host = executionhost1[0]/0*0+executionhost2/0*0+executionhost3/0*2
exec_vnode =
(executionhost1[0]:mem=1048576kb:ncpus=1+executionhost1[1]:mem=1048576kb:ncpus=1+executionho
st1[2]:ncpus=1)+(executionhost2:mem=104
8576kb:ncpus=1+executionhost2[0]:mem=1048576k:ncpus=1+executionhost2[1]:ncpus=1)+(executionhost3
:ncpus=2:mem=2097152kb)
Resource_List.mem = 6gb
Resource_List.ncpus = 8
Resource_List.nodect = 3
Resource_List.place = scatter
Resource_List.select = ncpus=3:mem=2gb+ncpus=3:mem=2gb+ncpus=2:mem=2gb
schedselect = 1:ncpus=3:mem=2gb+1:ncpus=3:mem=2gb+1:ncpus=2:mem=2gb
% pbs_release_nodes -j 241 executionhost2[1] executionhost3
% qstat 241 | grep "exec|Resource_List|select"
exec_host = executionhost1[0]/0*0+executionhost2/0*0 (no executionhost3; all assigned vnodes in
executionhost3 have been released)
exec_vnode =
(executionhost1[0]:mem=1048576kb:ncpus=1+executionhost1[1]:mem=1048576kb:ncpus=1+executionho
st1[2]:ncpus=1)+(executionhost2:mem=1048576kb:ncpus=1+executionhost2[0]:mem=1048576kb:ncpus=
1) (executionhost2[1] and executionhost3 no longer appear)
Resource_List.mem = 4194304kb (reduced by 2gb from executionhost3)
Resource_List.ncpus = 5 (reduced by 3 CPUs, 1 from executionhost2[1] and 2 from executionhost3)
Resource_List.nodect = 2 (reduced by 1 chunk; when executionhost3 was released, its entire chunk assignment
disappeared)
Resource_List.place = scatter
schedselect = 1:mem=2097152kb:ncpus=3+1:mem=2097152kb:ncpus=2
```

Example 6-6: Release all vnodes not on the primary execution host:

---

```
Syntax: pbs_release_nodes [-j <job ID>] -a
% pbs_release_nodes -j 241 -a
% qstat -f 241
exec_host = executionhost1[0]/0*0
exec_vnode =
 (executionhost1[0]:mem=1048576kb:ncpus=1)+executionhost1[1]:mem=1048576kb:ncpus=1+executionh
 ost1[2]:ncpus=1)
Resource_List.mem = 2097152kb
Resource_List.ncpus = 3
Resource_List.nodect = 1
Resource_List.place = scatter
schedselect = 1:mem=2097152kb:ncpus=3
```

Example 6-7: Release all sister hosts except for 4:

```
% pbs_release_nodes -k 4
```

Example 6-8: Release all sister vnodes except for 8 of those marked with “bigmem”:

```
% pbs_release_nodes -k select=8:bigmem=true
```

Example 6-9: Sister vnodes are no longer listed in \$PBS\_NODEFILE after they are released:

```
% qsub -l select=2:ncpus=1:mem=1gb -l place=scatter -I
qsub: waiting for job 247.executionhost1.example.com to start
qsub: job 247.executionhost1.example.com ready
% cat $PBS_NODEFILE
executionhost1.example.com
executionhost2.example.com
% pbs_release_nodes -j 247 executionhost2
% cat $PBS_NODEFILE
executionhost1.example.com
```

## 6.15 Running Your Job in a Container

PBS supports running multi-vnode, multi-host, and interactive jobs in Docker and Singularity containers.

You can specify a container engine by requesting a resource whose value is set to that engine, or you can use the default by not requesting one. You can request only one container engine per job, even though this resource is requested at the host level. You must request the same container engine for all chunks. Ask your administrator for the name of the resource listing available container engines, or find it using `pbsnodes` (look for container engine names). We recommend that this resource is named “container engine”.

```
qsub ... -l select=ncpus=...:<container engine resource>=<container engine>
```

You request a container image for your job via `-l container_image=<container image>` or by setting the `CONTAINER_IMAGE` environment variable to the name of the image and passing the environment variable with the job:

```
qsub ... -l container_image=<container image> ...
```

or

```
qsub ... -v CONTAINER_IMAGE=<name of container image> ...
```

Example 6-10: To request the Docker container engine and an image named “centos”:

```
qsub -l select=1:ncpus=1:container_engine=docker -lcontainer_image="centos" -- /bin/sleep 500
```

If you do not specify a script, for example “qsub -l container\_image=hello-world”, qsub asks you interactively for a script.

If you supply a script to qsub, PBS runs the script inside the specified container.

For a multi-host job, you can use any version of OpenMPI with containers.

PBS runs an infinite-duration sleep command in the container to keep the container alive.

## 6.15.1 Specifying Ports with Docker Containers

For single-vnode jobs in Docker containers, you can request ports for applications. PBS maps requested ports to available ports on the host and returns the mapping. You request ports by listing comma-separated port numbers in the container\_ports job resource. Lists of port numbers must be enclosed in single quotes. PBS sets the job’s resources\_used.container\_ports value to comma-separated <container port>:<host port> pairs. For example, your job can request specific ports:

```
qsub -l container_ports="'2324,8989'" ...
```

PBS returns the port mapping in the job’s resources\_used.container\_ports resource:

```
resources_used.container_ports = 2324:8080,8989:32771
```

## 6.15.2 Specifying Additional Arguments to Container Engine

You can specify additional arguments to the container engine via the PBS\_CONTAINER\_ARGS environment variable, which is a semicolon-separated list. For example, to specify --shm-size to be 1GB and --tmpfs to be “/run:rw,noexec,nosuid,size=65536k”:

```
export PBS_CONTAINER_ARGS="--shm-size=1GB";"--tmpfs /run:rw,noexec,nosuid,size=65536k"
```

Your PBS administrator must whitelist any additional arguments before you use them in a job.

The --env and --entrypoint arguments to docker run are not supported.

## 6.15.3 Passing Environment Variables Into Containers

To pass environment variables directly to PBS, use qsub -v <environment variable list>. The --env argument is not supported.

## 6.15.4 Adding Job Owner to Secondary Groups in Docker Containers

Your administrator can configure PBS to add the job owner to secondary groups inside the container. These are the groups on the execution host where the job owner is already a member. This feature applies only to Docker containers, since Singularity automatically adds the job owner to all groups.

---

### 6.15.5 Running Single-vnode Single-Host Jobs in Singularity Containers

In addition to using PBS to launch your containers, you can always run a single-vnode job in a single Singularity container by prepending your scripts, executables, or commands with the Singularity binary.

### 6.15.6 Specifying Shell in Container

You can run your default shell inside a container without taking any extra steps. To run a shell in a container using anything besides the default, you must specify the shell using the `-S` option to `qsub`. Any selected shell should be available inside the container.

### 6.15.7 Caveats and Restrictions

- You cannot use old-style resource requests such as `-lncpus` with containers.
- Any entry point in a container is disabled. If you want to run the equivalent of an entry point command, you must include the complete command with its arguments on the command line.

## 6.16 Running Your Job in the Cloud

To submit a job that can run in the cloud, submit it to the configured cloud queue. Syntax:

```
qsub -q <name of cloud queue> -l <resource request> <job script>
```

For example:

```
qsub -q cloudq -- /bin/sleep 100
```

### 6.16.1 Restrictions and Caveats for Cloud Bursting with PBS

- Cloud bursting is supported only on Linux.
- Reservations are not supported on cloud nodes.

## 6.17 Allowing Your Job to Tolerate Vnode Failures

You can allow your job to tolerate vnode failures if your administrator has configured PBS to do so. PBS lets you allocate extra vnodes to a job so that the job can successfully start and run even if some vnodes fail. PBS can allocate the extra vnodes only for startup, or for the life of the job. Later, for jobs where the extra vnodes are needed only for reliable startup, PBS can trim the allocated vnodes back to just what the job will use to run, releasing the unneeded vnodes for other jobs.

To allow your job to tolerate vnode failures during startup only, set the job's `tolerate_node_failures` attribute to `"start"`.

To allow your job to tolerate vnode failures during the life of the job, set the job's `tolerate_node_failures` attribute to `"all"`.

Examples of setting this attribute:

- Via qsub:  
`qsub -W tolerate_node_failures="all" <job script>`
- Via qalter:  
`qalter -W tolerate_node_failures="job_start" <job ID>`

# Reserving Resources

In this chapter we go over job reservations only (advance, standing, and job-specific reservations); maintenance reservations are covered in ["Reservations" on page 197 in the PBS Professional Administrator's Guide](#).

## 7.1 Glossary

### Advance reservation

A reservation for a set of resources for a specified time. The reservation is available only to the creator of the reservation and any users or groups specified by the creator.

### Degraded reservation

A job-specific or advance reservation for which one or more associated vnodes are unavailable.

A standing reservation for which one or more vnodes associated with any occurrence are unavailable.

### Job-specific reservation

A reservation created for a specific job, for the same resources that the job requested.

### Job-specific ASAP reservation

Reservation created for a specific queued job, for the same resources the job requests. PBS schedules the reservation to run as soon as possible, and PBS moves the job into the reservation. Created when you use `pbs_rsub -Wqmove=<job ID>` on a queued job.

### Job-specific now reservation

Reservation created for a specific running job. PBS immediately creates a job-specific now reservation on the same resources as the job is using, and moves the job into the reservation. The reservation is created and starts running immediately when you use `pbs_rsub --job <job ID>` on a running job.

### Job-specific start reservation

Reservation created for a specific queued job, for the same resources the job requests. PBS starts the job according to scheduling policy. When the job starts, PBS creates and starts the reservation, and PBS moves the job into the reservation. Created when you use `qsub -Wcreate_resv_from_job=true` on a queued job.

### Occurrence of a standing reservation

An instance of the standing reservation.

An occurrence of a standing reservation behaves like an advance reservation, with the following exceptions:

- while a job can be submitted to a specific advance reservation, it can only be submitted to the standing reservation as a whole, not to a specific occurrence. You can only specify *when* the job is eligible to run. See ["qsub" on page 213 of the PBS Professional Reference Guide](#).
- when an advance reservation ends, it and all of its jobs, running or queued, are deleted, but when an occurrence ends, only its running jobs are deleted.

Each occurrence of a standing reservation has reserved resources which satisfy the resource request, but each occurrence may have its resources drawn from a different source. A query for the resources assigned to a standing reservation will return the resources assigned to the soonest occurrence, shown in the `resv_nodes` attribute reported by `pbs_rstat`.

**Soonest occurrence of a standing reservation**

The occurrence which is currently active, or if none is active, then it is the next occurrence.

**Standing reservation**

An advance reservation which recurs at specified times. For example, you can reserve 8 CPUs and 10GB every Wednesday and Thursday from 5pm to 8pm, for the next three months.

## 7.2 Quick Explanation of Reservations for Jobs

You can reserve resources to be used later by jobs, or you can create a reservation using the resources requested by a specific job, and move the job into that reservation.

You create an advance or standing reservation, then submit jobs to the reservation. An **advance reservation** reserves specific resources for a specific time period, and a **standing reservation** does the same thing, but for a repeating sequence of time periods.

PBS creates **job-specific reservations** by reserving the same resources that a queued job requests, or a running job is using, then moving the job into the reservation's queue.

- PBS creates [Job-specific Start Reservations](#) for specific queued jobs whose `create_resv_from_job` attribute is `True`. When the job runs, PBS creates and starts the reservation, and PBS moves the job into the reservation. This reservation allows you to re-run the job later without having to wait for it to be scheduled again. You can set this attribute at submission using `qsub -Wcreate_resv_from_job=true`.
- PBS creates [Job-specific ASAP Reservations](#) for specific queued jobs when you use `pbs_rsub -Wqmove=<job ID>` on those jobs. PBS creates the reservation and moves the job into the reservation, and the reservation is scheduled to run as soon as possible.
- PBS creates [Job-specific Now Reservations](#) for specific running jobs when you use `pbs_rsub --job <job ID>` on them. PBS immediately creates a reservation, starts it, and moves the job into the reservation. This reservation allows you to re-run the job without having to wait for it to be scheduled again.

## 7.3 Prerequisites for Reserving Resources

The time for which a reservation is requested is in the time zone at the submission host.

You must set the submission host's `PBS_TZID` environment variable. The format for `PBS_TZID` is a timezone location. Example: `America/Los_Angeles`, `America/Detroit`, `Europe/Berlin`, `Asia/Kolkata`. See [section 1.4.4, "Setting Time Zone for Submission Host", on page 9](#).

## 7.4 Advance and Standing Reservations

### 7.4.1 Introduction to Creating and Using Advance and Standing Reservations

You can create both advance and standing reservations using the `pbs_rsub` command. PBS either confirms that the reservation can be made, or rejects the request. Once the reservation is confirmed, PBS creates a queue for the reservation's jobs. Jobs are then submitted to this queue.

When a reservation is confirmed, it means that the reservation will not conflict with currently running jobs, other confirmed reservations, or dedicated time, and that the requested resources are available for the reservation. A reservation request that fails these tests is rejected. All occurrences of a standing reservation must be acceptable in order for the standing reservation to be confirmed.

The `pbs_rsub` command returns a *reservation ID*, which is the reservation name. For an advance reservation, this reservation ID has the format:

*R*<sequence number>.<server name>

For a standing reservation, this reservation ID refers to the entire series, and has the format:

*S*<sequence number>.<server name>

You specify the resources for a reservation using the same syntax as for a job. Jobs in reservations are placed the same way non-reservation jobs are placed in placement sets.

The time for which a reservation is requested is in the time zone at the submission host.

The `pbs_rsub` command returns a reservation ID string, and the current status of the reservation.

You can create an advance or standing reservation so that if the reservation sits idle, it is automatically deleted after the amount of time you specify. For a standing reservation, this applies to each occurrence separately. If one occurrence of a standing reservation is deleted, the next occurrence still starts at its designated time. To have your reservation be deleted automatically, use `pbs_rsub -Wdelete_idle_time=<allowed idle time>` and specify the number of seconds as an integer, or the duration as *HH:MM:SS*.

For the options to the `pbs_rsub` command, see [“pbs\\_rsub” on page 96 of the PBS Professional Reference Guide](#).

## 7.4.2 Creating Advance Reservations

You create an advance reservation using the `pbs_rsub` command. PBS must be able to calculate the start and end times of the reservation, so you must specify two of the following three options:

- D Duration
- E End time
- R Start time

### 7.4.2.1 Setting Time Zone for Advance Reservations

If you need the time zone for your advance reservation to be UTC, set this when you create the reservation:

```
TZ=UTC pbs_rsub -R...
```

### 7.4.2.2 Examples of Creating Advance Reservations

The following example shows the creation of an advance reservation asking for 1 vnode, 30 minutes of wall-clock time, and a start time of 11:30. Since an end time is not specified, PBS will calculate the end time based on the reservation start time and duration.

```
pbs_rsub -R 1130 -D 00:30:00
```

PBS returns the reservation ID:

```
R226.south UNCONFIRMED
```

The following example shows an advance reservation for 2 CPUs from 8:00 p.m. to 10:00 p.m.:

```
pbs_rsub -R 2000.00 -E 2200.00 -l select=1:ncpus=2
```

PBS returns the reservation ID:

```
R332.south UNCONFIRMED
```

### 7.4.3 Creating Standing Reservations

You create standing reservations using the `pbs_rsub` command. You **must** specify a start and end date when creating a standing reservation. The recurring nature of the reservation is specified using the `-r` option to `pbs_rsub`. The `-r` option takes the `recurrence_rule` argument, which specifies the standing reservation's occurrences. The recurrence rule uses iCalendar syntax, and uses a subset of the parameters described in RFC 2445.

The recurrence rule can take two forms:

```
"FREQ=<freq spec>;COUNT=<count spec>;<interval spec>"
```

In this form, you specify how often there will be occurrences, how many there will be, and which days and/or hours apply.

```
"FREQ=<freq spec>;UNTIL=<until spec>;<interval spec>"
```

Do not include any spaces in your recurrence rule.

In this form, you specify how often there will be occurrences, when the occurrences will end, and which days and/or hours apply.

#### *freq spec*

This is the frequency with which the reservation repeats. Valid values are **WEEKLY|DAILY|HOURLY**

When using a *freq spec* of **WEEKLY**, you may use an *interval spec* of **BYDAY** and/or **BYHOUR**. When using a *freq spec* of **DAILY**, you may use an *interval spec* of **BYHOUR**. When using a *freq spec* of **HOURLY**, do not use an *interval spec*.

#### *count spec*

The exact number of occurrences. Number up to 4 digits in length. Format: integer.

#### *interval spec*

Specifies the interval at which there will be occurrences. Can be one or both of **BYDAY=<days>** or **BYHOUR=<hours>**. Valid values are **BYDAY = MO|TU|WE|TH|FR|SA|SU** and **BYHOUR = 0|1|2|...|23**. When using both, separate them with a semicolon. Separate days or hours with a comma.

For example, to specify that there will be recurrences on Tuesdays and Wednesdays, at 9 a.m. and 11 a.m., use **BYDAY=TU,WE;BYHOUR=9,11**

**BYDAY** should be used with **FREQ=WEEKLY**. **BYHOUR** should be used with **FREQ=DAILY** or **FREQ=WEEKLY**.

#### *until spec*

Occurrences will start up to but not after this date and time. This means that if occurrences last for an hour, and normally start at 9 a.m., then a time of 9:05 a.m. on the day specified in the *until spec* means that an occurrence will start on that day.

Format: **YYYYMMDD[THHMMSS]**

Note that the year-month-day section is separated from the hour-minute-second section by a capital **T**.

Default: 3 years from time of reservation creation.

#### 7.4.3.1 Setting Reservation Start Time and Duration

In a standing reservation, the arguments to the `-R` and `-E` options to `pbs_rsub` can provide more information than they do in an advance reservation. In an advance reservation, they provide the start and end time of the reservation. In a standing reservation, they can provide the start and end time, but they can also be used to compute the duration and the offset from the interval start.

The difference between the values of the arguments for `-R` and `-E` is the duration of the reservation. For example, if you specify

```
-R 0930 -E 1145
```

the duration of your reservation will be two hours and fifteen minutes. If you specify

```
-R 150800 -E 170830
```

the duration of your reservation will be two days plus 30 minutes.

The *interval spec* can be used to specify the day or the hour at which the interval starts. If you specify

```
-R 0915 -E 0945 ... BYHOUR=9,10
```

the duration is 30 minutes, and the offset is 15 minutes from the start of the interval. The interval start is at 9 and again at 10. Your reservation will run from 9:15 to 9:45, and again at 10:15 and 10:45. Similarly, if you specify

```
-R 0800 -E -1000 ... BYDAY=WE,TH
```

the duration is two hours and the offset is 8 hours from the start of the interval. Your reservation will run Wednesday from 8 to 10, and again on Thursday from 8 to 10.

Elements specified in the recurrence rule override those specified in the arguments to the -R and -E options. Therefore if you specify

```
-R 0730 -E 0830 ... BYHOUR=9
```

the duration is one hour, but the hour element (9:00) in the recurrence rule has overridden the hour element specified in the argument to -R (7:00). The offset is still 30 minutes after the interval start. Your reservation will run from 9:30 to 10:30. Similarly, if the 16th is a Monday, and you specify

```
-R 160800 -E 170900 ... BYDAY=TU;BYHOUR=11
```

the duration 25 hours, but both the day and the hour elements have been overridden. Your reservation will run on Tuesday at 11, for 25 hours, ending Wednesday at 12. However, if you specify

```
-R 160810 -E 170910 ... BYDAY=TU;BYHOUR=11
```

the duration is 25 hours, and the offset from the interval start is 10 minutes. Your reservation will run on Tuesday at 11:10, for 25 hours, ending Wednesday at 12:10. The minutes in the offset weren't overridden by anything in the recurrence rule.

The values specified for the arguments to the -R and -E options can be used to set the start and end times in a standing reservation, just as they are in an advance reservation. To do this, don't override their elements inside the recurrence rule. If you specify

```
-R 0930 -E 1030 ... BYDAY=MO,TU
```

you haven't overridden the hour or minute elements. Your reservation will run Monday and Tuesday, from 9:30 to 10:30.

### 7.4.3.2 Requirements for Creating Standing Reservations

- You must specify a start and end date.
- You must set the submission host's `PBS_TZID` environment variable. The format for `PBS_TZID` is a timezone location. Example: `America/Los_Angeles`, `America/Detroit`, `Europe/Berlin`, `Asia/Calcutta`. See [section 1.4.4, "Setting Time Zone for Submission Host", on page 9](#).
- The recurrence rule must be one unbroken line.
- The recurrence rule must be enclosed in double quotes.
- Vnodes that have been configured to accept jobs only from a specific queue (vnode-queue restrictions) cannot be used for advance or standing reservations. See your PBS administrator to determine whether some vnodes have been configured to accept jobs only from specific queues.
- Make sure that there are no spaces in your recurrence rule.

### 7.4.3.3 Examples of Creating Standing Reservations

For a reservation that runs every day from 8am to 10am, for a total of 10 occurrences:

```
pbs_rsub -R 0800 -E 1000 -r "FREQ=DAILY;COUNT=10"
```

Every weekday from 6am to 6pm until December 10, 2008:

```
pbs_rsub -R 0600 -E 1800 -r "FREQ=WEEKLY;BYDAY=MO,TU,WE,TH,FR;UNTIL=20081210"
```

Every week from 3pm to 5pm on Monday, Wednesday, and Friday, for 9 occurrences, i.e., for three weeks:

```
pbs_rsub -R 1500 -E 1700 -r "FREQ=WEEKLY;BYDAY=MO,WE,FR;COUNT=9"
```

## 7.5 Job-specific Reservations

### 7.5.1 Job-specific Start Reservations

PBS runs the job normally, and when the job starts, PBS creates and starts a *job-specific start reservation* and moves the job into the reservation. PBS creates the reservation using the same resources that are being used by the job. The reservation holds the resources needed for the job in case the job fails and needs to be re-submitted, allowing it to run again without having to wait to be scheduled. The reservation starts when the job starts and has the same end time as the job.

If you have a queued job that you think is likely to fail and need to be corrected and re-submitted, you can create a job-specific *start reservation*. When you submit the job, set its `create_resv_from_job` attribute to *True* using the `-W` option to `qsub`:

```
qsub ... -Wcreate_resv_from_job=true
```

For example, to create a job-specific start reservation for the job whose script is named `myscript.sh`:

```
qsub myscript.sh -Wcreate_resv_from_job=true
```

You can also `qalter` a queued job to set this attribute:

```
qalter -Wcreate_resv_from_job=true <job ID>
```

For example, to create a start reservation when job `1234.myserver` starts:

```
qalter -Wcreate_resv_from_job=true 1234.myserver
```

A job-specific start reservation ID has the format:

```
R<sequence number>.<server name>
```

PBS sets the start reservation's `reserve_job` attribute to the ID of the job from which the reservation was created, sets the reservation's `Reserve_Owner` attribute to the value of the job's `Job_Owner` attribute, sets the reservation's `resv_nodes` attribute to the job's `exec_vnode` attribute, sets the reservation's resources to the job's `schedselect` attribute, and sets the reservation's `Resource_List` attribute to the job's `Resource_List` attribute.

The start reservation's duration and start time are the same as the job's walltime and start time. If the job is peer scheduled, the now reservation is created in the pulling complex.

The start reservation is created when the job begins execution. You can set the `create_resv_from_job` attribute to *True* at any time, but this is only effective if you do it before the job starts. If your job has started running and you want to create a job-specific reservation for it, create a job-specific now reservation; see [section 7.5.3, "Job-specific Now Reservations", on page 141](#).

Can be used only with queued jobs.

Cannot be used with job arrays, jobs being submitted to other reservations, or other users' jobs.

## 7.5.2 Job-specific ASAP Reservations

PBS schedules a *job-specific ASAP reservation* to start as soon as possible. PBS creates a *job-specific ASAP reservation* using the resources requested by a specific queued job, and moves the job into the reservation.

Other jobs can also be moved into that queue via `qmove` or submitted to that queue via `qsub`.

To create an ASAP reservation:

```
pbs_rsub -W qmove=<job ID>
```

For example, to create an ASAP reservation for job 1234.myserver:

```
pbs_rsub -W qmove="1234.myserver"
```

A job-specific ASAP reservation ID has the format:

```
R<sequence number>.<server name>
```

The `-R` and `-E` options to `pbs_rsub` are disabled when using the `-W qmove` option.

Cannot be used on job arrays.

For more information, see [“pbs\\_rsub” on page 96 of the PBS Professional Reference Guide](#).

We recommend using ASAP reservations only for sites that set job walltime. A job’s default walltime is 5 years. Therefore an ASAP reservation’s start time can be 5 years later, or more, if all the jobs in the system have the default walltime.

The [delete idle time](#) attribute for an ASAP reservation has a default value of 10 minutes.

## 7.5.3 Job-specific Now Reservations

PBS creates and starts a *job-specific now reservation* on the same resources used by a running job, and moves the running job into the reservation. The reservation holds the resources needed for the job in case the job fails and needs to be re-submitted, allowing it to run again without having to wait to be scheduled.

If you realize that a running job needs modification and re-submitting, and you don’t want to have to wait until the scheduler finds a slot, you can create a now reservation. Later, you can submit a modified version of the job into the reservation:

```
pbs_rsub --job <job ID>
```

For example, to create a now reservation for job 1234.myserver while it’s running:

```
pbs_rsub --job 1234.myserver
```

A job-specific now reservation ID has the format:

```
R<sequence number>.<server name>
```

PBS sets the job’s `create_resv_from_job` attribute to *True*, sets the now reservation’s `reserve_job` attribute to the ID of the job from which the reservation was created, sets the reservation’s `Reserve_Owner` attribute to the value of the job’s `Job_Owner` attribute, sets the reservation’s `resv_nodes` attribute to the job’s `exec_vnode` attribute, sets the reservation’s resources to the job’s `schedselect` attribute, and sets the reservation’s `Resource_List` attribute to the job’s `Resource_List` attribute.

The now reservation’s duration and start time are the same as the job’s walltime and start time. If the job is peer scheduled, the now reservation is created in the pulling complex.

Can be used on running jobs only (jobs in the *R* state, with substate 42).

Cannot be used with job arrays, jobs already in reservations, or other users’ jobs.

## 7.6 Getting Confirmation of a Reservation

By default the `pbs_rsub` command does not immediately notify you whether the reservation is confirmed or denied. Instead you receive email with this information. You can specify that the `pbs_rsub` command should wait for confirmation by using the `-I <block time>` option. The `pbs_rsub` command will wait up to *block time* seconds for the reservation to be confirmed or denied and then notify you of the outcome. If *block time* is negative and the reservation is not confirmed in that time, the reservation is automatically deleted.

To find out whether the reservation has been confirmed, use the `pbs_rstat` command. It will display the state of the reservation. `CO` and `RESV_CONFIRMED` indicate that it is confirmed. If the reservation does not appear in the output from `pbs_rstat`, that means that the reservation was denied.

To ensure that you receive mail about your reservations, set the reservation's `Mail_Users` attribute via the `-M <email address>` option to `pbs_rsub`. By default, you will get email when the reservation is terminated or confirmed. If you want to receive email about events other than those, set the reservation's `Mail_Points` attribute via the `-m <mail events>` option. For more information, see [“pbs\\_rsub” on page 96 of the PBS Professional Reference Guide](#) and [“Reservation Attributes” on page 303 of the PBS Professional Reference Guide](#).

## 7.7 Modifying Reservations

You can use the `pbs_ralter` command to alter an existing reservation. You can use this command to modify a job-specific reservation or an advance reservation or the next or current instance of a standing reservation. Syntax:

```
pbs_ralter [-D <duration>] [-E <end time>] [-G <auth group list>] [-I <block time>] [-m <mail points>] [-M <mail list>] [-N <reservation name>] [-R <start time>] [-U <auth user list>] <reservation ID>
```

After the change is requested, the change is either confirmed or denied. On denial of the change, the reservation is not deleted and is left as is, and the following message appears in the server's log:

```
Unable to alter reservation <reservation ID>
```

When a reservation is confirmed, the following message appears in the server's log:

```
Reservation alter successful for <reservation ID>
```

To find out whether or not the change was allowed:

- Use the `pbs_rstat` command: see whether you altered reservation attribute(s)
- Use the interactive option: check for confirmation after the blocking time has run out

If the reservation has not started and it cannot be confirmed on the same vnodes, PBS searches for another set of vnodes. See [section 9.4, "Reservation Fault Tolerance", on page 426 of the PBS Professional Administrator's Guide](#).

You must be the reservation owner or the PBS Administrator to run this command.

For details, see [“pbs\\_ralter” on page 86 of the PBS Professional Reference Guide](#).

## 7.8 Deleting Reservations

You can delete a reservation by using the `pbs_rdel` command. For a standing reservation, you can only delete the entire reservation, including all occurrences. When you delete a reservation, all of the jobs that have been submitted to the reservation are also deleted. A reservation can be deleted by its owner or by a PBS Operator or Manager. For example, to delete `S304.south`:

```
pbs_rdel S304.south
```

or

```
pbs_rdel S304
```

You can create a reservation so that if the reservation sits idle, it is automatically deleted after the amount of time you specify. For a standing reservation, this applies to each occurrence separately. If one occurrence of a standing reservation is deleted, the next occurrence still starts at its designated time. To have your reservation be deleted automatically, use `pbs_rsub -Wdelete_idle_time=<allowed idle time>` and specify the number of seconds as an integer, or the duration as *HH:MM:SS*.

## 7.9 Viewing the Status of a Reservation

The following table shows the list of possible states for a reservation. The states that you will usually see are CO, UN, BD, and RN, although a reservation usually remains unconfirmed for too short a time to see that state. See [“Reservation States” on page 367 of the PBS Professional Reference Guide](#).

To view the status of a reservation, use the `pbs_rstat` command. It will display the status of all reservations at the PBS server. For a standing reservation, the `pbs_rstat` command will display the status of the soonest occurrence. Duration is shown in seconds. The `pbs_rstat` command will not display a custom resource which has been created to be invisible. See [section 4.3.8, “Caveats and Restrictions on Requesting Resources”, on page 57](#). This command has three options:

**Table 7-1: Options to `pbs_rstat` Command**

| Option | Meaning | Description                                                                                                     |
|--------|---------|-----------------------------------------------------------------------------------------------------------------|
| B      | Brief   | Lists only the names of the reservations                                                                        |
| S      | Short   | Lists in table format the name, queue name, owner, state, and start, duration and end times of each reservation |
| F      | Full    | Lists the name and all non-default-value attributes for each reservation.                                       |
| <none> | Default | Default is S option                                                                                             |

The full listing for a standing reservation is identical to the listing for an advance reservation, with the following additions:

- A line that specifies the recurrence rule:  
`reserve_rrule = FREQ=WEEKLY;BYDAY=MO;COUNT=5`
- An entry for the vnodes reserved for the soonest occurrence of the standing reservation. This entry also appears for an advance reservation, but will be different for each occurrence:  
`resv_nodes=(<vnode name>:...)`
- A line that specifies the total number of occurrences of the standing reservation:  
`reserve_count = 5`
- The index of the soonest occurrence:  
`reserve_index = 1`
- The timezone at the site of submission of the reservation is appended to the reservation’s `Variable_List` attribute. For example, in California:  
`Variable_List=<other variables>PBS_TZID=America/Los_Angeles`

To get the status of a reservation at a server other than the default server, set the `PBS_SERVER` environment variable to the name of the server you wish to query, then use the `pbs_rstat` command. Your PBS commands will treat the new server as the default server, so you may wish to unset this environment variable when you are finished.

You can also get information about the reservation's queue by using the `qstat` command. See [“qstat” on page 197 of the PBS Professional Reference Guide](#).

## 7.9.1 Examples of Viewing Reservation Status Using `pbs_rstat`

In our example, we have one advance reservation and one standing reservation. The advance reservation is for today, for two hours, starting at noon. The standing reservation is for every Thursday, for one hour, starting at 3:00 p.m. Today is Monday, April 28th, and the time is 1:00, so the advance reservation is running, and the soonest occurrence of the standing reservation is Thursday, May 1, at 3:00 p.m.

Example brief output:

```
pbs_rstat -B
Name: R302.south
Name: S304.south
```

Example short output:

```
pbs_rstat -S

Name Queue User State Start / Duration / End

R302.south R302 user1 RN Today 12:00 / 7200/ Today 14:00
S304.south S304 user1 CO May 1 2008 15:00/3600/May 1 2008 16:00
```

---

Example full output:

```
pbs_rstat -F
Name: R302.south
Reserve_Name = NULL
Reserve_Owner = user1@south.mydomain.com
reserve_state = RESV_RUNNING
reserve_substate = 5
reserve_start = Mon Apr 28 12:00:00 2008
reserve_end = Mon Apr 28 14:00:00 2008
reserve_duration = 7200
queue = R302
Resource_List.ncpus = 2
Resource_List.nodect = 1
Resource_List.walltime = 02:00:00
Resource_List.select = 1:ncpus=2
Resource_List.place = free
resv_nodes = (south:ncpus=2)
Authorized_Users = user1@south.mydomain.com
server = south
ctime = Mon Apr 28 11:00:00 2008
Mail_Users = user1@mydomain.com
mtime = Mon Apr 28 11:00:00 2008
Variable_List = PBS_O_LOGNAME=user1,PBS_O_HOST=south.mydomain.com
```

```
Name: S304.south
Reserve_Name = NULL
Reserve_Owner = user1@south.mydomain.com
reserve_state = RESV_CONFIRMED
reserve_substate = 2
reserve_start = Thu May 1 15:00:00 2008
reserve_end = Thu May 1 16:00:00 2008
reserve_duration = 3600
queue = S304
Resource_List.ncpus = 2
Resource_List.nodect = 1
Resource_List.walltime = 01:00:00
Resource_List.select = 1:ncpus=2
Resource_List.place = free
resv_nodes = (south:ncpus=2)
reserve_rrule = FREQ=WEEKLY;BYDAY=MO;COUNT=5
reserve_count = 5
reserve_index = 2
Authorized_Users = user1@south.mydomain.com
server = south
ctime = Mon Apr 28 11:01:00 2008
Mail_Users = user1@mydomain.com
```

```
mtime = Mon Apr 28 11:01:00 2008
```

```
Variable_List = PBS_O_LOGNAME=user1,PBS_O_HOST=south.mydomain.com,PBS_TZID=America/Los_Angeles
```

## 7.10 Submitting a Job to a Reservation

Jobs can be submitted to the queue associated with a reservation, or they can be moved from another queue into the reservation queue. You submit a job to a reservation by using the `-q <queue>` option to the `qsub` command to specify the reservation queue. For example, to submit a job to the soonest occurrence of a standing reservation named `S123.south`, submit to its queue `S123`:

```
qsub -q S123 <script>
```

You move a job into a reservation queue by using the `qmove` command. For more information, see [“qsub” on page 213 of the PBS Professional Reference Guide](#) and [“qmove” on page 172 of the PBS Professional Reference Guide](#). For example, to `qmove` job `22.myhost` from `workq` to `S123`, the queue for the reservation named `S123.south`:

```
qmove S123 22.myhost
```

or

```
qmove S123 22
```

A job submitted to a standing reservation without a restriction on when it can run will be run, if possible, during the soonest occurrence. In order to submit a job to a specific occurrence, use the `-a <start time>` option to the `qsub` command, setting the start time to the time of the occurrence that you want. You can also use a `cron` job to submit a job at a specific time. See [“qsub” on page 213 of the PBS Professional Reference Guide](#) and the `cron(8)` man page.

### 7.10.1 Who Can Use Your Reservation

By default, the reservation accepts jobs only from the user who created the reservation, and accepts jobs submitted from any group or host. You can specify a list of users and groups whose jobs will and will not be accepted by the reservation by setting the reservation’s `Authorized_Users` and `Authorized_Groups` attributes using the `-U <authorized user list>` and `-G <authorized group list>` options to `pbs_rsub` and `pbs_ralter`. You can specify the hosts from which jobs can and cannot be submitted by setting the reservation’s `Authorized_Hosts` attribute using the `-H <authorized host list>` option to `pbs_rsub`.

The administrator can also specify which users and groups can and cannot submit jobs to a reservation, and the list of hosts from which jobs can and cannot be submitted.

For more information, see [“pbs\\_rsub” on page 96 of the PBS Professional Reference Guide](#) and [“Reservation Attributes” on page 303 of the PBS Professional Reference Guide](#).

### 7.10.2 Viewing Status of a Job Submitted to a Reservation

You can view the status of a job that has been submitted to a reservation or to an occurrence of a standing reservation by using the `qstat` command. See [“qstat” on page 197 of the PBS Professional Reference Guide](#).

For example, if a job named `MyJob` has been submitted to the soonest occurrence of the standing reservation named `S304.south`, it is listed under `S304`, the name of the queue:

```
qstat
```

| Job id    | Name  | User  | Time Use | S  | Queue |
|-----------|-------|-------|----------|----|-------|
| -----     | ----- | ----- | -----    | -- | ----- |
| 139.south | MyJob | user1 | 0        | Q  | S304  |

### 7.10.3 How Reservations Treat Jobs

A confirmed reservation will accept jobs into its queue at any time. Jobs are only scheduled to run from the reservation once the reservation period arrives.

The jobs in a reservation are not allowed to use, in aggregate, more resources than the reservation requested. A reservation job is accepted in the reservation regardless of whether its requested walltime will fit within the reservation period. So for example if the reservation runs from 10:00 to 11:00, and the job's walltime is 4 hours, the job will be started.

When an advance reservation ends, any running or queued jobs in that reservation are deleted.

When an occurrence of a standing reservation ends, any running jobs in that reservation are killed. Any jobs still queued for that reservation are kept in the queued state. They are allowed to run in future occurrences. When the last occurrence of a standing reservation ends, all jobs remaining in the reservation are deleted, whether queued or running.

A job in a reservation cannot be preempted.

A job in a reservation runs with the normal job environment variables; see [section 6.12, "Using Environment Variables", on page 126](#).

#### 7.10.3.1 Caveats for How Reservations Treat Jobs

If you submit a job to a reservation, and the job's walltime fits within the reservation period, but the time between when you submit the job and when the reservation ends is less than the job's walltime, PBS will start the job, and then kill it if it is still running when the reservation ends.

## 7.11 Reservation Caveats and Errors

### 7.11.1 Time Zone Must be Correct

The environment variable `PBS_TZID` must be set at the submission host. The time for which a reservation is requested is the time defined at the submission host. See [section 1.4.4, "Setting Time Zone for Submission Host", on page 9](#).

### 7.11.2 Time Required Between Reservations

Leave enough time between reservations for the reservations and jobs in them to clean up. A job consumes resources even while it is in the `E` or exiting state. This can take longer when large files are being staged. If the job is still running when the reservation ends, it may take up to two minutes to be cleaned up. The reservation itself cannot finish cleaning up until its jobs are cleaned up. This will delay the start time of jobs in the next reservation unless there is enough time between the reservations for cleanup.

### 7.11.3 Reservation Information in the Accounting Log

The PBS server writes an accounting record for each reservation in the job accounting file. The accounting record for a reservation is similar to that for a job. The accounting record for any job belonging to a reservation will include the reservation ID. See ["Accounting" on page 607 in the PBS Professional Administrator's Guide](#).

### 7.11.4 Reservation Fault Tolerance

If one or more vnodes allocated to a job-specific reservation, an advance reservation, or to the soonest occurrence of a standing reservation become unavailable, the reservation's state becomes `DG` or `RESV_DEGRADED`. A degraded reservation does not have all the reserved resources to run its jobs.

PBS attempts to reconfirm degraded reservations. This means that it looks for alternate available vnodes on which to run the reservation. The reservation's `retry_time` attribute lists the next time when PBS will try to reconfirm the reservation.

If PBS is able to reconfirm a degraded reservation, the reservation's state becomes *CO*, or *RESV\_CONFIRMED*, and the reservation's `resv_nodes` attribute shows the new vnodes.

### 7.11.5 Job and Reservation Exclusivity Must Match

If your job requests exclusive placement, and it is in a reservation, the reservation must also request exclusive placement via `-l place=excl`.

# Job Arrays

## 8.1 Advantages of Job Arrays

PBS provides job arrays, which are useful for collections of almost-identical jobs. Each job in a job array is called a “subjob”. Subjobs are scheduled and treated just like normal jobs, with the exceptions noted in this chapter. You can group closely related work into a set so that you can submit, query, modify, and display the set as a unit. Job arrays are useful where you want to run the same program over and over on different input files. PBS can process a job array more efficiently than it can the same number of individual normal jobs. Job arrays are suited for SIMD operations, for example, parameter sweep applications, rendering in media and entertainment, EDA simulations, and forex (historical data).

## 8.2 Glossary

### Job array identifier

The identifier returned upon success when submitting a job array. Format:

*<sequence number>[]*

### Job array range

A set of subjobs within a job array. When specifying a range, indices used must be valid members of the job array’s indices.

### Sequence number

The numeric part of a job or job array identifier, e.g. *1234*.

### Subjob

Individual entity within a job array (e.g. *1234[7]*, where *1234[]* is the job array itself, and *7* is the index) which has many properties of a job as well as additional semantics (defined below.)

### Subjob index

The unique index which differentiates one subjob from another. This must be a non-negative integer.

## 8.3 Description of Job Arrays

A job array is a compact representation of two or more jobs. A job that is part of a job array is called a “subjob”. Each subjob in a job array is treated exactly like a normal job, except for any differences noted in this chapter.

### 8.3.1 Job Script for Job Arrays

All subjobs in a job array share a single job script, including the PBS directives and the shell script portion. The job script is run once for each subjob.

The job script may invoke different commands based on the subjob index. The commands of course may be scripts themselves if the script is setup correctly and is marked executable. This could be done by naming different commands with the subjob index as in your example or by “if” statements in the script.

## 8.3.2 Attributes and Resources for Job Arrays

All subjobs in one job array have the same attributes, including resource requirements and limits.

The same job script runs for each subjob in the job array, so each subjob gets the same attributes and resources. If the job script calls other scripts or commands, those scripts or commands cannot change the attributes and resources for individual subjobs, because PBS stops processing directives when it starts processing commands.

## 8.3.3 Scheduling Job Arrays and Subjobs

The scheduler handles each subjob in a job array as a separate job. All subjobs within a job array have the same scheduling priority.

### 8.3.3.1 Starving

A job array's starving status is based on the queued portion of the array. This means that if there is a queued subjob which is starving, the job array is starving. A running subjob retains the starving status it had when it was started.

## 8.3.4 Identifier Syntax

The sequence number (1234 in 1234[<server>]) is unique, so that jobs and job arrays cannot share a sequence number. The job identifiers of the subjobs in the same job array are the same except for their indices. Each subjob has a unique index. You can refer to job arrays or parts of job arrays using the following syntax forms:

- The job array object itself: The format is *<sequence number>[<server>]* or *<sequence number>[<server>.<domain>].com*  
Example: 1234[.myserver] or 1234[.myserver.com]
- A single subjob with index *M*: The format is *<sequence number>[M]* or *<sequence number>[M].<server>.<domain>.com*  
Example where *M=17*: 1234[17].myserver or 1234[17].myserver.com
- A range of subjobs of a job array: The format is *<sequence number>[start-end[:step]]* or *<sequence number>[start-end[:step]].<server>.<domain>.com*  
Example where we start at 2, end at 8, and the step is 3: 1234[2-8:3].myserver or 1234[2-8:3].myserver.com

### 8.3.4.1 Examples of Using Identifier Syntax

|                              |                                                              |
|------------------------------|--------------------------------------------------------------|
| 1234[                        | Short job array identifier                                   |
| 1234[.myserver.domain.com    | Full job array identifier                                    |
| 1234[73]                     | Short subjob identifier of the 73rd index of job array 1234[ |
| 1234[73].myserver.domain.com | Full subjob identifier of the 73rd index of job array 1234[  |

### 8.3.4.2 Shells and Array Identifiers

Since some shells, for example `csh` and `tcsh`, read “[” and “]” as shell metacharacters, job array names and subjob names must be enclosed in double quotes for all PBS commands.

**Example:**

```
qdel "1234 [5] .myhost"
qdel "1234 [] .myhost"
```

Single quotes will work, except where you are using shell variable substitution.

### 8.3.5 Special Attributes for Job Arrays

Job arrays and subjobs have all of the attributes of a job. In addition, they have the following when appropriate. These attributes are read-only.

**Table 8-1: Job Array Attributes**

| Name                    | Type    | Applies To | Value                                                                                                              |
|-------------------------|---------|------------|--------------------------------------------------------------------------------------------------------------------|
| array                   | Boolean | Job array  | <i>True</i> if item is job array                                                                                   |
| array_id                | String  | Subjob     | Subjob's job array identifier                                                                                      |
| array_index             | String  | Subjob     | Subjob's index number                                                                                              |
| array_state_count       | String  | Job array  | Similar to <code>state_count</code> attribute for server and queue objects. Lists number of subjobs in each state. |
| array_indices_remaining | String  | Job array  | List of indices of subjobs still queued. Range or list of ranges, e.g. <i>500, 552, 596-1000</i>                   |
| array_indices_submitted | String  | Job array  | Complete list of indices of subjobs given at submission time. Given as range, e.g. <i>1-100</i>                    |

### 8.3.6 Job Array States

The state of subjobs in the same job array can be different. See [“Job Array States” on page 363 of the PBS Professional Reference Guide](#) and [“Subjob States” on page 364 of the PBS Professional Reference Guide](#).

### 8.3.7 PBS Environmental Variables for Job Arrays

**Table 8-2: PBS Environmental Variables for Job Arrays**

| Environment Variable Name | Used For      | Description                                                                                                               |
|---------------------------|---------------|---------------------------------------------------------------------------------------------------------------------------|
| PBS_ARRAY_INDEX           | Subjobs       | Subjob index in job array, e.g. <i>7</i>                                                                                  |
| PBS_ARRAY_ID              | Subjobs       | Identifier for a job array. Sequence number of job array, e.g. <i>1234[]</i> .myserver                                    |
| PBS_JOBID                 | Jobs, subjobs | Identifier for a job or a subjob. For subjob, sequence number and subjob index in brackets, e.g. <i>1234[7]</i> .myserver |

### 8.3.8 Accounting

Job accounting records for job arrays and subjobs are the same as for jobs. When a job array has been moved from one server to another, the subjob accounting records are split between the two servers.

Subjobs do not have “Q” records.

---

### 8.3.9 Prologues and Epilogues

If defined, prologues and epilogues run at the beginning and end of each subjob, but not for the array object.

### 8.3.10 The Rerunnable Flag and Job Arrays

Job arrays are required to be rerunnable. PBS will not accept a job array that is marked as not rerunnable. You can submit a job array without specifying whether it is rerunnable, and PBS will automatically mark it as rerunnable.

## 8.4 Submitting a Job Array

### 8.4.1 Job Array Submission Syntax

You submit a job array through a single command. You specify subjob indices at submission. You can specify any of the following:

- A contiguous range, e.g. 1 through 100
- A range with a stepping factor, e.g. every second entry in 1 through 100 (1, 3, 5, ... 99)

Syntax for submitting a job array:

```
qsub -J <index start>-<index end>[:<stepping factor>]
```

where

*index start* is the lowest index number in the range

*index end* is the highest index number in the range

*stepping factor* is the optional difference between index numbers

The index start and end must be whole numbers, and the stepping factor must be a positive integer. The index end must be greater than the index start. If the index end is not a multiple of the stepping factor above the index start, it will not be used as an index value, and the highest index value used will be lower than the index end. For example, if index start is 1, index end is 8, and the stepping factor is 3, the index values are 1, 4, and 7.

### 8.4.2 Examples of Submitting Job Arrays

Example 8-1: To submit a job array of 10,000 subjobs, with indices 1, 2, 3, ... 10000:

```
$ qsub -J 1-10000 job.scr
1234[] .server.domain.com
```

Example 8-2: To submit a job array of 500 subjobs, with indices 500, 501, 502, ... 1000:

```
$ qsub -J 500-1000 job.scr
1235[] .server.domain.com
```

Example 8-3: To submit a job array with indices 1, 3, 5 ... 999:

```
$ qsub -J 1-1000:2 job.scr
1236[] .server.domain.com
```

### 8.4.3 File Staging for Job Arrays

When preparing files to be staged for a job array, plan on naming the files so that they match the index numbers of the subjobs. For example, `inputfile3` is meant to be used by the subjob with index value 3.

To stage files for job arrays, you use the same mechanism as for normal jobs, but include a variable to specify the subjob index. This variable is named `array_index`.

#### 8.4.3.1 File Staging Syntax for Job Arrays

You can specify files to be staged in before the job runs and staged out after the job runs. Format:

```
qsub -W stagein=<stagein file list> -W stageout=<stageout file list>
```

You can use these as options to `qsub`, or as directives in the job script.

For both stagein and stageout, the *file list* has the form:

```
<execution path>^array_index^@<storage host>:<storage path>^array_index^[...]
```

The name `<execution path><index number>` is the name of the file in the job's staging and execution directory (on the execution host). The *execution path* can be relative to the job's staging and execution directory, or it can be an absolute path.

The '@' character separates the execution specification from the storage specification.

The name `<storage path><index number>` is the file name on the host specified by *storage host*. For stagein, this is the location where the input files come from. For stageout, this is where the output files end up when the job is done. You must specify a *storage host*. The name can be absolute, or it can be relative to your home directory on the storage machine.

For stagein, the direction of travel is **from storage path to execution path**.

For stageout, the direction of travel is **from execution path to storage path**.

When staging more than one set of filenames, separate the filenames with a comma and enclose the entire list in double quotes.

#### 8.4.3.2 Job Array Staging Syntax on Windows

In Windows the stagein and stageout string must be contained in double quotes when using `^array_index^`.

Example of a stagein:

```
qsub -W stagein="foo.^array_index^@host-1:C:\WINNT\Temp\foo.^array_index^" -J 1-5 stage_script
```

Example of a stageout:

```
qsub -W stageout="C:\WINNT\Temp\foo.^array_index^@host-1:Q:\my_username\foo.^array_index^_out" -J 1-5 stage_script
```

#### 8.4.3.3 Job Array File Staging Caveats

We recommend using an absolute pathname for the *storage path*. Remember that the path to your home directory may be different on each machine, and that when using `sandbox = PRIVATE`, you may or may not have a home directory on all execution machines.

#### 8.4.3.4 Examples of Staging for Job Arrays

Example 8-4: Simple example:

```
Storage path: store:/film
```

Data files used as input: frame1, frame2, frame3

execution path: pix

Executable: a.out

For this example, a.out produces frame2.out from frame2.

```
#PBS -W stagein=pix/in/frame^array_index@store:/film/frame^array_index^
#PBS- W stageout=pix/out/frame^array_index^.out @store:/film/frame^array_index^.out
#PBS -J 1-3 a.out frame$PBS_ARRAY_INDEX ./in ./out
```

Note that the stageout statement is all one line.

The result is that your directory named “film” contains the original files frame1, frame2, frame3, plus the new files frame1.out, frame2.out, and frame3.out.

Example 8-5: In this example, we have a script named ArrayScript which calls scriptlet1 and scriptlet2.

All three scripts are located in /homedir/testdir.

```
#!/bin/sh
#PBS -N ArrayExample
#PBS -J 1-2
echo "Main script: index " $PBS_ARRAY_INDEX
/homedir/testdir/scriptlet$PBS_ARRAY_INDEX
```

In our example, scriptlet1 and scriptlet2 simply echo their names. We run ArrayScript using the qsub command:

**qsub ArrayScript**

Example 8-6: In this example, we have a script called StageScript. It takes two input files, dataX and extraX, and makes an output file, newdataX, as well as echoing which iteration it is on. The dataX and extraX files will be staged from inputs to work, then newdataX will be staged from work to outputs.

```
#!/bin/sh
#PBS -N StagingExample
#PBS -J 1-2
#PBS -W stagein="/homedir/work/data^array_index^@host1:/homedir/inputs/data^array_index^, \
/homedir/work/extra^array_index^ @host1:/homedir/inputs/extra^array_index^"
#PBS -W stageout=/homedir/work/newdata^array_index^@host1:/homedir/outputs/newdata^array_index^
echo "Main script: index " $PBS_ARRAY_INDEX
cd /homedir/work
cat data$PBS_ARRAY_INDEX extra$PBS_ARRAY_INDEX >> newdata$PBS_ARRAY_INDEX
```

Execution path:

/homedir/work

Storage host:

host1

Storage path for inputs (original data files dataX and extraX):

/homedir/inputs

Storage path for results (output of computation newdataX):

/homedir/outputs

StageScript resides in /homedir/testdir. In that directory, we can run it by typing:

**qsub StageScript**

It will run in /homedir, our home directory, which is why the line

```
"cd /homedir/work"
```

is in the script.

Example 8-7: In this example, we have the same script as before, but we will run it in a staging and execution directory created by PBS. StageScript takes two input files, `dataX` and `extraX`, and makes an output file, `newdataX`, as well as echoing which iteration it is on. The `dataX` and `extraX` files will be staged from `inputs` to the staging and execution directory, then `newdataX` will be staged from the staging and execution directory to `outputs`.

```
#!/bin/sh
#PBS -N StagingExample
#PBS -J 1-2
#PBS -W stagein="data^array_index^@host1:/homedir/inputs/data^array_index^, \
 extra^array_index^@host1:/homedir/inputs/extra^array_index^"
#PBS -W stageout=newdata^array_index^@host1:/homedir/outputs/newdata^array_index^
echo "Main script: index " $PBS_ARRAY_INDEX
cat data$PBS_ARRAY_INDEX extra$PBS_ARRAY_INDEX >> newdata$PBS_ARRAY_INDEX
```

Execution path (directory): created by PBS; we don't know the name

Storage host:

```
host1
```

Storage path for inputs (original data files `dataX` and `extraX`):

```
/homedir/inputs
```

Storage path for results (output of computation `newdataX`):

```
/homedir/outputs
```

StageScript resides in /homedir/testdir. In that directory, we can run it by typing:

```
qsub StageScript
```

It will run in the staging and execution directory created by PBS. See [section 3.2, "Input/Output File Staging", on page 31](#).

## 8.4.4 Filenames for Standard Output and Standard Error

The name for `stdout` for a subjob defaults to `<job name>.o<sequence number>.<index>`, and the name for `stderr` for a subjob defaults to `<job name>.e<sequence number>.<index>`.

Example 8-8: The job is named "fixgamma" and the sequence number is "1234".

The subjob with index 7 is `1234[7].<server name>`. For this subjob, `stdout` and `stderr` are named `fixgamma.o1234.7` and `fixgamma.e1234.7`.

## 8.4.5 Job Array Dependencies

Job dependencies are supported for the following relationships:

- Between job arrays and job arrays
- Between job arrays and jobs
- Between jobs and job arrays

### 8.4.5.1 Caveats for Job Array Dependencies

Job dependencies are not supported for subjobs or ranges of subjobs.

## 8.4.6 Job Array Exit Status

The exit status of a job array is determined by the status of each of the completed subjobs. It is only available when all valid subjobs have completed. The individual exit status of a completed subjob is passed to the epilogue, and is available in the 'E' accounting log record of that subjob.

**Table 8-3: Job Array Exit Status**

| Exit Status | Meaning                                                                                                              |
|-------------|----------------------------------------------------------------------------------------------------------------------|
| 0           | All subjobs of the job array returned an exit status of 0. No PBS error occurred. Deleted subjobs are not considered |
| 1           | At least 1 subjob returned a non-zero exit status. No PBS error occurred.                                            |
| 2           | A PBS error occurred.                                                                                                |

### 8.4.6.1 Making `qsub` Wait Until Job Array Finishes

Blocking `qsub` waits until the entire job array is complete, then returns the exit status of the job array.

### 8.4.6.2 Caveats for Job Array Exit Status

Subjob exit status is available only as long as the subjob is in job history. When a subjob is not in job history, a failed or terminated subjob will show an exit status of *Finished*, instead of failed or terminated.

## 8.4.7 Caveats for Submitting Job Arrays

### 8.4.7.1 No Interactive Job Submission of Job Arrays

Interactive submission of job arrays is not allowed.

## 8.5 Viewing Status of a Job Array

You can use the `qstat` command to query the status of a job array. The default output is to list the job array in a single line, showing the job array identifier. You can combine options.

You can use the `-f` option to the `qstat` command to see all of a subjob's attributes.

To show the state of all running subjobs, use `-t -r`. To show the state of subjobs only, not job arrays, use `-t -J`.

**Table 8-4: Job Array and Subjob Options to `qstat`**

| Option | Result                                                                                                                                                                                                                                    |
|--------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| -t     | Shows state of job array object and subjobs.<br>Also shows state of jobs.                                                                                                                                                                 |
| -J     | Shows state only of job arrays.                                                                                                                                                                                                           |
| -p     | Prints the default display, with column for Percentage Completed.<br>For a job array, this is the number of subjobs completed or deleted divided by the total number of subjobs.<br>For a job, it is time used divided by time requested. |

## 8.5.1 Example of Viewing Job Array Status

We run an example job and an example job array, on a machine with 2 processors:

demoscript:

```
#!/bin/sh
#PBS -N JobExample
sleep 60
```

arrayscript:

```
#!/bin/sh
#PBS -N ArrayExample
#PBS -J 1-5
sleep 60
```

We run these scripts using `qsub`:

```
qsub arrayscript
1235[].host
qsub demoscript
1236.host
```

We query using various options to `qstat`:

#### `qstat`

| Job id       | Name         | User  | Time Use | S | Queue |
|--------------|--------------|-------|----------|---|-------|
| 1235[ ].host | ArrayExample | user1 | 0        | B | workq |
| 1236.host    | JobExample   | user1 | 0        | Q | workq |

#### `qstat -J`

| Job id       | Name         | User  | Time Use | S | Queue |
|--------------|--------------|-------|----------|---|-------|
| 1235[ ].host | ArrayExample | user1 | 0        | B | workq |

#### `qstat -p`

| Job id       | Name         | User  | % done | S | Queue |
|--------------|--------------|-------|--------|---|-------|
| 1235[ ].host | ArrayExample | user1 | 0      | B | workq |
| 1236.host    | JobExample   | user1 | --     | Q | workq |

#### `qstat -t`

| Job id       | Name         | User  | Time Use | S | Queue |
|--------------|--------------|-------|----------|---|-------|
| 1235[ ].host | ArrayExample | user1 | 0        | B | workq |
| 1235[1].host | ArrayExample | user1 | 00:00:00 | R | workq |
| 1235[2].host | ArrayExample | user1 | 00:00:00 | R | workq |
| 1235[3].host | ArrayExample | user1 | 0        | Q | workq |
| 1235[4].host | ArrayExample | user1 | 0        | Q | workq |
| 1235[5].host | ArrayExample | user1 | 0        | Q | workq |
| 1236.host    | JobExample   | user1 | 0        | Q | workq |

#### `qstat -Jt`

| Job id       | Name         | User  | Time Use | S | Queue |
|--------------|--------------|-------|----------|---|-------|
| 1235[1].host | ArrayExample | user1 | 00:00:00 | R | workq |
| 1235[2].host | ArrayExample | user1 | 00:00:00 | R | workq |
| 1235[3].host | ArrayExample | user1 | 0        | Q | workq |
| 1235[4].host | ArrayExample | user1 | 0        | Q | workq |
| 1235[5].host | ArrayExample | user1 | 0        | Q | workq |

After the first two subjobs finish:

```
qstat -Jtp
Job id Name User % done S Queue

1235[1].host ArrayExample user1 100 X workq
1235[2].host ArrayExample user1 100 X workq
1235[3].host ArrayExample user1 -- R workq
1235[4].host ArrayExample user1 -- R workq
1235[5].host ArrayExample user1 -- Q workq
```

```
qstat -pt
Job id Name User % done S Queue

1235[].host ArrayExample user1 40 B workq
1235[1].host ArrayExample user1 100 X workq
1235[2].host ArrayExample user1 100 X workq
1235[3].host ArrayExample user1 -- R workq
1235[4].host ArrayExample user1 -- R workq
1235[5].host ArrayExample user1 -- Q workq
1236.host JobExample user1 -- Q workq
```

Now if we wait until only the last subjob is still running:

```
qstat -rt
Job ID Username Queue Jobname SessID NDS TSK Memory Req'd Req'd Elap

1235[5].host user1 workq ArrayExamp 3048 -- 1 -- -- R 00:00
1236.host user1 workq JobExample 3042 -- 1 -- -- R 00:00
```

```
qstat -Jrt
Job ID Username Queue Jobname SessID NDS TSK Memory Req'd Req'd Elap

1235[5].host user1 workq ArrayExamp 048 -- 1 -- -- R 00:01
```

## 8.6 Using PBS Commands with Job Arrays

The following table shows how you can or cannot use PBS commands with job arrays, subjobs or ranges:

**Table 8-5: Using PBS Commands with Job Arrays**

| Command  | Argument to Command            |                                          |                                |
|----------|--------------------------------|------------------------------------------|--------------------------------|
|          | Array[]: Array Object          | Array[Range]: Specified Range of Subjobs | Array[Index]: Specified Subjob |
| qalter   | Array object                   | erroneous                                | erroneous                      |
| qdel     | Array object & Running subjobs | Running subjobs in specified range       | Specified subjob               |
| qhold    | Array object & Queued subjobs  | erroneous                                | erroneous                      |
| qmove    | Array object & Queued subjobs  | erroneous                                | erroneous                      |
| qmsg     | erroneous                      | erroneous                                | erroneous                      |
| qorder   | Array object                   | erroneous                                | erroneous                      |
| qrerun   | Running and finished subjobs   | Running subjobs in specified range       | Specified subjob               |
| qrls     | Array object & Queued subjobs  | erroneous                                | erroneous                      |
| qsig     | Running subjobs                | Running subjobs in specified range       | Specified subjob               |
| qstat    | Array object                   | Specified range of subjobs               | Specified subjob               |
| tracejob | erroneous                      | erroneous                                | Specified subjob               |

### 8.6.1 Deleting a Job Array

The `qdel` command will take a job array identifier, subjob identifier or job array range. The indicated object(s) are deleted, including any currently running subjobs. Running subjobs are treated like running jobs. Subjobs not running are deleted and never run.

By default, one email is sent per deleted subjob, so deleting a job array of 5000 subjobs results in 5000 emails being sent, unless you are suppressing the number of emails sent. See [“-Wsuppress\\_email=<N>” on page 141 of the PBS Professional Reference Guide](#).

### 8.6.2 Altering a Job Array

The `qalter` command can only be used on a job array object, not on subjobs or ranges. Job array attributes are the same as for jobs.

### 8.6.3 Moving a Job Array

The `qmove` command can only be used with job array objects, not with subjobs or ranges. Job arrays can only be moved from one server to another if they are in the ‘Q’, ‘H’, or ‘W’ states, and only if there are no running subjobs. The state of the job array object is preserved in the move. The job array will run to completion on the new server.

As with jobs, a `qstat` on the server from which the job array was moved does not show the job array. A `qstat` on the job array object is redirected to the new server.

## 8.6.4 Holding a Job Array

The `qhold` command can only be used with job array objects, not with subjobs or ranges. A hold can be applied to a job array only from the ‘*Q*’, ‘*B*’ or ‘*W*’ states. This puts the job array in the ‘*H*’, held, state. If any subjobs are running, they will run to completion. No queued subjobs are started while in the ‘*H*’ state.

If a job array has subjobs that have a System hold, the job array also gets a System hold.

## 8.6.5 Releasing a Job Array

The `qrls` command can be used directly only with job array objects, not with subjobs or ranges. If the job array was in the ‘*Q*’ or ‘*B*’ state, it is returned to that state. If it was in the ‘*W*’ state, it is returned to that state, unless its waiting time was reached, in which case it goes to the ‘*Q*’ state.

You can use `qrls` indirectly on subjobs. If you use `qrls` on a job array, and that job array has a System hold because it has subjobs(s) with a System hold, the subjobs that were held with a System hold are released, then the System hold on the job array is released (you’ll need Manager, root, or PBS Administrator privilege for this).

## 8.6.6 Selecting Job Arrays

The default behavior of `qselect` is to return the job array identifier, without returning subjob identifiers.

The `qselect` command does not return any job arrays when the state selection (`-s`) option restricts the set to ‘*R*’, ‘*S*’, ‘*T*’ or ‘*U*’, because a job array will never be in any of these states. However, you can use `qselect` to return a list of subjobs by using the `-t` option.

You can combine options to `qselect`. For example, to restrict the selection to subjobs, use both the `-J` and the `-T` options. To select only running subjobs, use `-J -T -sR`.

**Table 8-6: Options to `qselect` for Job Arrays**

| Option          | Selects          | Result                              |
|-----------------|------------------|-------------------------------------|
| (none)          | jobs, job arrays | Shows job and job array identifiers |
| <code>-J</code> | job arrays       | Shows only job array identifiers    |
| <code>-T</code> | jobs, subjobs    | Shows job and subjob identifiers    |

## 8.6.7 Ordering Job Arrays in the Queue

The `qorder` command can only be used with job array objects, not on subjobs or ranges. This changes the queue order of the job array in association with other jobs or job arrays in the queue.

## 8.6.8 Requeueing a Job Array

The `qrerun` command will take a job array identifier, subjob identifier or job array range. If a job array identifier is given as an argument, it is returned to its initial state at submission time, or to its altered state if it has been qaltered. All of that job array’s subjobs are requeued, which includes those that are currently running, and those that are completed and deleted. If a subjob or range is given, those subjobs are requeued as jobs would be.

## 8.6.9 Signaling a Job Array

If a job array object, subjob or job array range is given to `qsig`, all currently running subjobs within the specified set are sent the signal.

## 8.6.10 Sending Messages to Job Arrays

The `qmsg` command is not supported for job arrays.

## 8.6.11 Getting Log Data on Job Arrays

The `tracejob` command can be run on job arrays and individual subjobs. When `tracejob` is run on a job array or a subjob, the same information is displayed as for a job, with additional information for a job array. Note that subjobs do not exist until they are running, so `tracejob` will not show any information until they are. When `tracejob` is run on a job array, the information displayed is only that for the job array object, not the subjobs. Job arrays themselves do not produce any MoM log information. Running `tracejob` on a job array gives information about why a subjob did not start.

## 8.6.12 Caveats for Using PBS Commands with Job Arrays

### 8.6.12.1 Shells and PBS Commands with Job Arrays

Some shells such as `csh` and `tcsh` use the square bracket (“[”, “]”) as a metacharacter. When using one of these shells, and a PBS command taking subjobs, job arrays or job array ranges as arguments, the subjob, job array or job array range must be enclosed in double quotes.

## 8.7 Job Array Caveats

### 8.7.1 Job Arrays Required to be Rerunnable

Job arrays are required to be rerunnable, and are rerunnable by default.

### 8.7.2 Resources Same for All Subjobs

You cannot combine jobs into an array that have different hardware requirements, i.e. different select statements.

### 8.7.3 Checkpointing Not Supported for Job Arrays

Checkpointing is not supported for job arrays. On systems that support checkpointing, subjobs are not checkpointed, instead they run to completion.

### 8.7.4 Caveats for Job Array Exit Status

Subjob exit status is available only as long as the subjob is in job history. When a subjob is not in job history, a failed or terminated subjob will show an exit status of *Finished*, instead of failed or terminated.

# Working with PBS Jobs

## 9.1 Using Job History

PBS Professional can provide job history information, including what the submission parameters were, whether the job started execution, whether execution succeeded, whether staging out of results succeeded, and which resources were used.

PBS can keep job history for jobs which have finished execution, were deleted, or were moved to another server.

### 9.1.1 Definitions

#### **Moved jobs**

Jobs which were moved to another server

#### **Finished jobs**

Jobs whose execution is done, for any reason:

- Jobs which finished execution successfully and exited
- Jobs terminated by PBS while running
- Jobs whose execution failed because of system or network failure
- Jobs which were deleted before they could start execution

### 9.1.2 Job History Information

PBS can keep all job attribute information, including the following:

- Submission parameters
- Whether the job started execution
- Whether execution succeeded
- Whether staging out of results succeeded
- Which resources were used

PBS keeps job history for the following jobs:

- Jobs that are running at another server
- Jobs that have finished execution
- Jobs that were deleted
- Jobs that were moved to another server

While a job is running, you can see information about it. After a job has finished or been deleted, its history information is preserved for the specified duration. The administrator chooses a duration for preservation of job history information after each job has finished or been deleted. PBS periodically checks each finished job, and deletes job history for those whose history has been preserved for longer than the specified duration.

Subjobs are not considered finished jobs until the parent array job is finished, which happens when all of its subjobs have terminated execution.

### 9.1.2.1 Working With Moved Jobs

You can use the following commands with moved jobs. They will function as they do with normal jobs.

```
qalter
qhold
qmove
qmsg
qorder
qrerun
qrlls
qrun
qsig
```

While a moved job is running, its state is *M*. When a moved job finishes, its substate becomes 92. See [“Job States” on page 361 of the PBS Professional Reference Guide](#).

### 9.1.2.2 PBS Commands and Finished Jobs

The commands listed above cannot be used with finished jobs, whether they finished at the local server or a remote server. These jobs are no longer running; PBS is storing their information, and this information cannot be altered. Trying to use one of the above commands with a finished job results in the following error message:

```
<command name>: Job <job ID> has finished
```

## 9.2 Modifying Job Attributes

Most attributes can be changed by the owner of the job (or a manager or operator) while the job is still queued. However, once a job begins execution, the only values that can be modified are *cputime*, *walltime*, and *run\_count*. You can decrease *walltime*, and you can increase *run\_count*.

When the `qalter -l` option is used to alter the resource list of a queued job, it is important to understand the interactions between altering the select directive and job limits.

If the job was submitted with an explicit `-l select=`, then vnode-level resources must be `qalter`d using the `-l select=` form. In this case a vnode level resource RES cannot be `qalter`d with the `-l <resource>` form.

For example:

Submit the job:

```
% qsub -l select=1:ncpus=2:mem=512mb jobscript
```

Job's ID is 230

`qalter` the job using `-l RES` form:

```
% qalter -l ncpus=4 230
```

Error reported by `qalter`:

```
qalter: Resource must only appear in "select"
specification when select is used: ncpus 230
```

`qalter` the job using the "-l select=" form:

```
% qalter -l select=1:ncpus=4:mem=512mb 230
```

No error reported by `qalter`:

```
%
```

## 9.2.1 Changing the Selection Directive

If the selection directive is altered, the job limits for any consumable resource in the directive are also modified.

For example, if a job is queued with the following resource list:

```
select=2:ncpus=1:mem=5gb
```

job limits are set to `ncpus=2`, `mem=10gb`.

If the select statement is altered to request:

```
select=3:ncpus=2:mem=6gb
```

then the job limits are reset to `ncpus=6` and `mem=18gb`

## 9.2.2 Changing the Job-wide Limit

If the job-wide limit is modified, the corresponding resources in the selection directive are not modified. It would be impossible to determine where to apply the changes in a compound directive.

Reducing a job-wide limit to a new value less than the sum of the resource in the directive is strongly discouraged. This may produce a situation where the job is aborted during execution for exceeding its limits. The actual effect of such a modification is not specified.

A job's walltime may be altered at any time, except when the job is in the *Exiting* state, regardless of the initial value.

If a job is queued, requested modifications must still fit within the queue's and server's job resource limits. If a requested modification to a resource would exceed the queue's or server's job resource limits, the resource request will be rejected.

Resources are modified by using the `-l` option, either in chunks inside of selection statements, or in job-wide modifications using `resource_name=value` pairs. The selection statement is of the form:

```
-l select=[N:]chunk[+[N:]chunk ...]
```

where `N` specifies how many of that chunk, and a chunk is of the form:

```
<resource name>=<value>[:<resource name>=<value> ...]
```

Job-wide `<resource name>=<value>` modifications are of the form:

```
-l <resource name>=<value>[,<resource name>=<value> ...]
```

Placement of jobs on vnodes is changed using the place statement:

```
-l place=<modifier>[:<modifier>]
```

where *modifier* is any combination of *group*, *excl*, *exclhost*, and/or one of *free|pack|scatter|vscatter*.

The usage syntax for `qalter` is:

```
qalter <job resources> <job list>
```

The following examples illustrate how to use the `qalter` command. First we list all the jobs of a particular user. Then we modify two attributes as shown (increasing the wall-clock time from 20 to 25 minutes, and changing the job name from “airfoil” to “engine”):

```
qstat -u barry
```

| Job ID   | User  | Queue | Jobname | Sess | NDS | TSK | Mem | Req'd Time | Elap Time |
|----------|-------|-------|---------|------|-----|-----|-----|------------|-----------|
| 51.south | barry | workq | airfoil | 930  | --  | 1   | --  | 0:16 R     | 0:01      |
| 54.south | barry | workq | airfoil | --   | --  | 1   | --  | 0:20 Q     | --        |

```
qalter -l walltime=20:00 -N engine 54
```

```
qstat -a 54
```

| Job ID   | User  | Queue | Jobname | Sess | NDS | TSK | Mem | Req'd Time | Elap Time |
|----------|-------|-------|---------|------|-----|-----|-----|------------|-----------|
| 54.south | barry | workq | engine  | --   | --  | 1   | --  | 0:25 Q     | --        |

The `qalter` command can be used on job arrays, but not on subjobs or ranges of subjobs. When used with job arrays, any job array identifiers must be enclosed in double quotes, e.g.:

```
qalter -l walltime=25:00 "1234[] .south"
```

You cannot use the `qalter` command (or any other command) to alter a custom resource which has been created to be invisible or unrequestable. See [section 4.3.8, “Caveats and Restrictions on Requesting Resources”, on page 57](#).

For more information, see [“qalter” on page 127 of the PBS Professional Reference Guide](#).

### 9.2.2.1 Caveats

Be careful when using a Boolean resource as a job-wide limit.

## 9.3 Deleting Jobs

PBS provides the `qdel` command for deleting jobs. The `qdel` command deletes jobs in the order in which their job identifiers are presented to the command. A batch job may be deleted by its owner, a PBS operator, or a PBS administrator. Unless you are an administrator or an operator, you can delete only your own jobs.

To delete a queued, held, running, or suspended job:

```
qdel <job ID>
```

Example:

```
qdel 51
qdel 1234[] .server
```

Job array identifiers must be enclosed in double quotes.

### 9.3.1 Deleting Jobs with Force

You can delete a job whether or not its execution host is reachable, and whether or not it is in the process of provisioning:

```
qdel -W force <job ID>
```

### 9.3.2 Deleting Finished Jobs

By default, the `qdel` command does not affect finished jobs. You can use the `qdel -x` option to delete job histories. This option also deletes any specified jobs that are queued, running, held, suspended, finished, or moved. When you use this, you are deleting the job and its history in one step. If you use the `qdel` command without the `-x` option, you delete the job, but not the job history, and you cannot delete a finished job.

To delete a finished job, whether or not it was moved:

```
qdel -x <job ID>
```

If you try to delete a finished job without the `-x` option, you will get the following error:

```
qdel: Job <job ID> has finished
```

### 9.3.3 Deleting Moved Jobs

You can use the `qdel -x` option to delete jobs that are queued, running, held, suspended, finished, or moved.

To delete a job that was moved:

```
qdel <job ID sequence number>.<original server>
```

To delete a job that was moved, and then finished:

```
qdel -x <job ID>
```

### 9.3.4 Restricting Number of Emails

By default, mail is sent for each job or subjob you delete. Use the following option to `qdel` to specify a limit on emails sent:

```
qdel -Wsuppress_email=<N>
```

See [section 2.5.1.3, “Restricting Number of Job Deletion Emails”, on page 27](#).

## 9.4 Sending Messages to Jobs

To send a message to a job is to write a message string into one or more output files of the job. Typically this is done to leave an informative message in the output of the job. Such messages can be written using the `qmsg` command.

You can send messages to running jobs only.

The usage syntax of the `qmsg` command is:

```
qmsg [-E][-O] <message string> <job ID>
```

Example:

```
qmsg -O "output file message" 54
qmsg -O "output file message" "1234[] .server"
```

Job array identifiers must be enclosed in double quotes.

The `-E` option writes the message into the error file of the specified job(s). The `-O` option writes the message into the output file of the specified job(s). If neither option is specified, the message will be written to the error file of the job.

The first operand, *message\_string*, is the message to be written. If the string contains blanks, the string must be quoted. If the final character of the string is not a newline, a newline character will be added when written to the job's file. All remaining operands are job IDs which specify the jobs to receive the message string. For example:

```
qmsg -E "hello to my error (.e) file" 55
qmsg -O "hello to my output (.o) file" 55
qmsg "this too will go to my error (.e) file" 55
```

## 9.5 Sending Signals to Jobs

You can use the `qsig` command to send a signal to your job. The signal is sent to all of the job's processes.

Usage syntax of the `qsig` command is:

```
qsig [-s <signal>] <job ID>
```

Job array *job IDs* must be enclosed in double quotes.

If the `-s` option is not specified, `SIGTERM` is sent. If the `-s` option is specified, it declares which *signal* is sent to the job. The *signal* argument is either a signal name, e.g. `SIGKILL`, the signal name without the *SIG* prefix, e.g. `KILL`, or an unsigned signal number, e.g. `9`. The signal name `SIGNULL` is allowed; the server will send the signal `0` to the job which will have no effect. Not all signal names will be recognized by `qsig`. If it doesn't recognize the signal name, try issuing the signal number instead. The request to signal a batch job will be rejected if:

- You are not authorized to signal the job
- The job is not in the running state
- The requested signal is not supported by the execution host
- The job is exiting
- The job is provisioning

Two special signal names, "suspend" and "resume", (note, all lower case), are used to suspend and resume jobs. When suspended, a job continues to occupy system resources but is not executing and is not charged for walltime. Manager or operator privilege is required to suspend or resume a job.

The signal `TERM` is useful, because it is ignored by shells, but you can trap it and do useful things such as write out status.

The three examples below all send a signal `9` (`SIGKILL`) to job `34`:

```
qsig -s SIGKILL 34
qsig -s KILL 34
```

If you want to trap the signal in your job script, the signal must be trapped by all of the job's shells.

On most Linux systems the command "`kill -l`" (that's 'minus ell') will list all the available signals.

## 9.6 Changing Order of Jobs

PBS provides the `qorder` command to change the order of two jobs, within or across queues. To order two jobs is to exchange the jobs' positions in the queue or queues in which the jobs reside. If job1 is at position 3 in queue A and job2 is at position 4 in queue B, qordering them will result in job1 being in position 4 in queue B and job2 being in position 3 in queue A.

No attribute of the job (such as `Priority`) is changed. The impact of changing the order within the queue(s) is dependent on local job scheduling policy; contact your systems administrator for details.

Usage of the `qorder` command is:

```
qorder <job ID>1 <job ID2>
```

Job array identifiers must be enclosed in double quotes.

Both operands are *job IDs* which specify the jobs to be exchanged.

```
qstat -u bob
```

| Job ID    | User | Queue | Jobname | Sess | NDS | TSK | Mem | Req'd Time | Elap S | Time |
|-----------|------|-------|---------|------|-----|-----|-----|------------|--------|------|
| 54.south  | bob  | workq | twinkie | --   | --  | 1   | --  | 0:20       | Q      | --   |
| 63[.south | bob  | workq | airfoil | --   | --  | 1   | --  | 0:13       | Q      | --   |

```
qorder 54 "63[" "
```

```
qstat -u bob
```

| Job ID    | User | Queue | Jobname | Sess | NDS | TSK | Mem | Req'd Time | Elap S | Time |
|-----------|------|-------|---------|------|-----|-----|-----|------------|--------|------|
| 63[.south | bob  | workq | airfoil | --   | --  | 1   | --  | 0:13       | Q      | --   |
| 54.south  | bob  | workq | twinkie | --   | --  | 1   | --  | 0:20       | Q      | --   |

## 9.6.1 Restrictions

- The two jobs must be located at the same server, and both jobs must be owned by you. However, a PBS Manager or Operator can exchange any jobs.
- A job in the running state cannot be reordered.
- The `qorder` command can be used with entire job arrays, but not on subjobs or ranges. Reordering a job array changes the queue order of the job array in relation to other jobs or job arrays in the queue.

## 9.7 Moving Jobs Between Queues

PBS provides the `qmove` command to move jobs between different queues (even queues on different servers). To move a job is to remove the job from the queue in which it resides and instantiate the job in another queue.

A job in the running state cannot be moved.

The usage syntax of the `qmove` command is:

```
qmove <destination> <job ID(s)>
```

Job array *<job ID>s* must be enclosed in double quotes.

The first operand is the new destination for

```
<queue>
@<server>
<queue>@<server>
```

If the *destination* operand describes only a queue, then `qmove` will move jobs into the queue of the specified name at the job's current server. If the *destination* operand describes only a server, then `qmove` will move jobs into the default queue at that server. If the *destination* operand describes both a queue and a server, then `qmove` will move the jobs into the specified queue at the specified server. All following operands are *job IDs* which specify the jobs to be moved to the new *destination*.

The `qmove` command can only be used with job array objects, not with subjobs or ranges. Job arrays can only be moved from one server to another if they are in the '*Q*', '*H*', or '*W*' states, and only if there are no running subjobs. The state of the job array object is preserved in the move. The job array will run to completion on the new server.

As with jobs, a `qstat` on the server from which the job array was moved will not show the job array. A `qstat` on the job array object will be redirected to the new server.

The subjob accounting records will be split between the two servers.

# Checking Job & System Status

## 10.1 Checking Job Status

You can use the `qstat` command to view job information in the following formats:

- Basic format: minimal summary of jobs
- Alternate format: intermediate listing of job information
- Long format: shows all information about jobs

You can see only the information for which you have the required privilege.

We discuss each format in the following sections. See [“qstat” on page 197 of the PBS Professional Reference Guide](#).

By default, `qstat` displays information for queued or running jobs only. However, you can tell `qstat` to display information for all jobs, whether they are running, queued, finished, or moved; we cover this in this chapter. Job history is kept for a period defined by your administrator.

Summary of usage:

### Displaying Job Status

Default format:

```
qstat [-E] [-J] [-p] [-t] [-x] [[<job ID> | <destination>] ...]
```

Long format:

```
qstat -f [-F json|dsv [-D <delimiter>]] [-E] [-J] [-p] [-t] [-w] [-x] [[<job ID> | <destination>] ...]
```

Alternate format:

```
qstat [-a [-w]] [-H | -i | -r] [-E] [-G | -M] [-J] [-n [-l] [-w]] [-s [-l] [-w]] [-t] [-T [-w]] [-u <user list>] [[<job ID> | <destination>] ...]
```

### Displaying Queue Status

Default format:

```
qstat -Q [<destination> ...]
```

Long format:

```
qstat -Q -f [-F json|dsv [-D <delimiter>]] [-w] [<destination> ...]
```

Alternate format:

```
qstat -q [-G | -M] [<destination> ...]
```

### Displaying Server Status

Default format:

```
qstat -B [<server> ...]
```

Long format:

```
qstat -B -f [-F json|dsv [-D <delimiter>]] [-w] [<server> ...]
```

```
qstat --version
```

## 10.1.1 Specifying Jobs to View

You can specify that you want information for a job identifier, a list of job identifiers, or all of the jobs at a destination.

To specify a job identifier, it must be in the following form:

```
<sequence number>[.<server>][@<server>]
```

where *<sequence number>*.*<server>* is the job identifier assigned at submission. If you do not specify *<server>*, the default server is used. If *@<server>* is supplied, the request will be for the job identifier currently at that server.

If you specify a destination identifier, it takes one of the following three forms:

```
<queue>
```

```
@<server>
```

```
<queue>@<server>
```

If you specify *<queue>*, the request is for status of all jobs in that queue at the default server.

If you use the *@<server>* form, the request is for status of all jobs at that server.

If you specify a full destination identifier, *<queue>@<server>*, the request is for status of all jobs in the named *queue* at the named *server*.

## 10.1.2 Viewing Default Job Status

You can use the `qstat` command to view basic job status, in the default format.

Syntax for simple form and with options:

```
qstat
```

```
qstat [-E] [-J] [-p] [-t] [-x] [[<job ID> | <destination>] ...]
```

The default display shows the following information:

- The job identifier assigned by PBS
- The job name given by the submitter
- The job owner
- The CPU time used
- The job state; see [“Job States” on page 361 of the PBS Professional Reference Guide](#).
- The queue in which the job resides

The following example illustrates the default display of `qstat`.

```
qstat
Job id Name User Time Use S Queue

16.south aims14 user1 0 H workq
18.south aims14 user1 0 W workq
26.south airfoil barry 00:21:03 R workq
27.south airfoil barry 21:09:12 R workq
28.south myjob user1 0 Q workq
29.south tns3d susan 0 Q workq
30.south airfoil barry 0 Q workq
31.south seq_35_3 donald 0 Q workq
```

### 10.1.3 Viewing Job Status in Alternate Format

You can use the `qstat` command to view more detail than the basic job information, in the alternate format.

Syntax for simple form and with options:

`qstat -a`

`qstat [-a [-w]] [-H | -i | -r ] [-E] [-G | -M] [-J] [-n [-l] [-w]] [-s [-l] [-w]] [-t] [-T [-w]] [-u <user list>] [[<job ID> | <destination>] ...]`

The alternate display shows the following fields:

- Job ID
- Job owner
- Queue in which job resides
- Job name
- Session ID (only appears when job is running)
- Number of chunks or vnodes requested
- Number of CPUs requested
- Amount of memory requested
- Amount of CPU time requested, if CPU time requested; if not, amount of wall clock time requested
- State of job
- Amount of CPU time elapsed, if CPU time requested; if not, amount of wall clock time elapsed

`qstat -a`

Job ID	User	Queue	Jobname	Ses	NDS	TSK	Mem	Time	S	Time
16.south	user1	workq	aims14	--	--	1	--	0:01	H	--
18.south	user1	workq	aims14	--	--	1	--	0:01	W	--
51.south	barry	workq	airfoil	930	--	1	--	0:13	R	0:01
52.south	user1	workq	myjob	--	--	1	--	0:10	Q	--
53.south	susan	workq	tns3d	--	--	1	--	0:20	Q	--
54.south	barry	workq	airfoil	--	--	1	--	0:13	Q	--
55.south	donald	workq	seq_35_	--	--	1	--	2:00	Q	--

You can use the `-l` option to reformat `qstat` output to a single line. This option can only be used in conjunction with the `-n` and/or `-s` options.

### 10.1.3.1 Display Size in Gigabytes

The “-G” option to `qstat` displays all jobs at the requested or default server using the alternative display, showing all size information in gigabytes (GB) rather than the default of smallest displayable units. Note that if the size specified is less than 1 GB, then the amount is rounded up to 1 GB. For example:

```
qstat -G
host1:
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Req'd Mem	Req'd Time	Elap S	Time
43.host1	user1	workq	STDIN	4693	1	1	--	--	R	00:05
44[ ].host1	user1	workq	STDIN	--	1	1	--	--	Q	--
45.host1	user1	workq	STDIN	--	1	1	1gb	--	Q	--

### 10.1.3.2 Display Size in Megawords

The “-M” option to `qstat` displays all jobs at the requested (or default) server using the alternative display, showing all size information in megawords (MW) rather than the default of smallest displayable units. A word is considered to be 8 bytes. For example:

```
qstat -M
host1:
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Req'd Mem	Req'd Time	Elap S	Time
43.host1	user1	workq	STDIN	4693	1	1	--	--	R	00:05
44[ ].host1	user1	workq	STDIN	--	1	1	--	--	Q	--
45.host1	user1	workq	STDIN	--	1	1	25mw	--	Q	--

## 10.1.4 Viewing Job Status in Long Format

You can use the `qstat` command to view all of the information about a job, including values for its attributes and resources, in the long format.

Syntax for simple form and with options:

```
qstat -f
```

```
qstat -f [-F json|dsv [-D <delimiter>]] [-E] [-J] [-p] [-t] [-w] [-x] [[<job ID> | <destination>] ...]
```

You can see job status in JSON or delimiter-separated value formats; see [section 10.4, “Full Display Options for Job, Queue, and Server Status”](#), on page 186. The long format shows the following fields, including job attributes. See [“Job Attributes” on page 328 of the PBS Professional Reference Guide](#) for a description of attributes:

```
qstat -f 13
Job Id: 13.host1
 Job_Name = STDIN
 Job_Owner = user1@host2
 resources_used.cpuspercent = 0
 resources_used.cput = 00:00:00
 resources_used.mem = 2408kb
 resources_used.ncpus = 1
 resources_used.vmem = 12392kb
 resources_used.walltime = 00:01:31
 job_state = R
 queue = workq
 server = host1
 Checkpoint = u
 ctime = Thu Apr 2 12:07:05 2010
 Error_Path = host2:/home/user1/STDIN.e13
 exec_host = host2/0
 exec_vnode = (host3:ncpus=1)
 Hold_Types = n
 Join_Path = n
 Keep_Files = n
 Mail_Points = a
 mtime = Thu Apr 2 12:07:07 2010
 Output_Path = host2:/home/user1/STDIN.o13
 Priority = 0
 qtime = Thu Apr 2 12:07:05 2010
 Rerunable = True
 Resource_List.ncpus = 1
 Resource_List.nodect = 1
 Resource_List.place = free
 Resource_List.select = host=host3
 stime = Thu Apr 2 12:07:08 2010
 session_id = 32704
 jobdir = /home/user1
 substate = 42
 Variable_List = PBS_O_HOME=/home/user1,PBS_O_LANG=en_US.UTF-8,
 PBS_O_LOGNAME=user1,
 PBS_O_PATH=/opt/gnome/sbin:/root/bin:/usr/local/bin:/usr/bin:/usr/X11R
 6/bin:/bin:/usr/games:/opt/gnome/bin:/opt/kde3/bin:/usr/lib/mit/bin:/us
 r/lib/mit/sbin,PBS_O_MAIL=/var/mail/root,PBS_O_SHELL=/bin/bash,
 PBS_O_HOST=host2,PBS_O_WORKDIR=/home/user1,PBS_O_SYSTEM=Linux,
 PBS_O_QUEUE=workq
 comment = Job run at Thu Apr 02 at 12:07 on (host3:ncpus=1)
```

```

alt_id = <dom0:job ID xmlns:dom0="http://schemas.microsoft.com/HPCS2008/hpcb
p">149</dom0:Job ID>
etime = Thu Apr 2 12:07:05 2010
Submit_arguments = -lselect=host=host3 -- ping -n 100 127.0.0.1
executable = <jsdl-hpcpa:Executable>ping</jsdl-hpcpa:Executable>
argument_list = <jsdl-hpcpa:Argument>-n</jsdl-hpcpa:Argument><jsdl-hpcpa:Ar
gument>100</jsdl-hpcpa:Argument><jsdl-hpcpa:Argument>127.0.0.1</jsdl-hp
cpa:Argument>

```

### 10.1.4.1 Path Display under Windows

When you view a job in long format that was submitted from a mapped drive, PBS displays the UNC path for the job's Output\_Path, Error\_Path attributes, and the value for PBS\_O\_WORKDIR in the job's Variable\_List attribute.

When you view a job in long format that was submitted using UNC paths for output and error files, PBS displays the UNC path for the job's Output\_Path and Error\_Path attributes.

## 10.1.5 Listing Jobs by User

The “-u” option to `qstat` displays jobs owned by any of a list of user names you specify.

Syntax:

```
qstat -u <user name>[@<host>][,<user name>[@<host>],...]
```

Host names are not required, and may be “wild carded” on the left end, e.g. “\*.mydomain.com”. <user name> without a “@<host>” is equivalent to “<user name>@\*”, that is at any host.

```
qstat -u user1
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Elap Time
16.south	user1	workq	aims14	--	--	1	--	0:01 H	--
18.south	user1	workq	aims14	--	--	1	--	0:01 W	--
52.south	user1	workq	my_job	--	--	1	--	0:10 Q	--

```
qstat -u user1,barry
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Elap Time
51.south	barry	workq	airfoil	930	--	1	--	0:13 R	0:01
52.south	user1	workq	my_job	--	--	1	--	0:10 Q	--
54.south	barry	workq	airfoil	--	--	1	--	0:13 Q	--

## 10.1.6 Listing Running Jobs

The “-r” option to `qstat` displays the status of all running jobs at the (optionally specified) PBS server. Running jobs include those that are running and suspended. One line of output is generated for each job reported, and the information is presented in the alternative display. For example:

```
qstat -r
host1:

```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Req'd S	Elap Time
43.host1	user1	workq	STDIN	4693	1	1	--	--	R	00:00

## 10.1.7 Listing Non-Running Jobs

The “-i” option to `qstat` displays the status of all non-running jobs at the (optionally specified) PBS server. Non-running jobs include those that are queued, held, and waiting. One line of output is generated for each job reported, and the information is presented in the alternative display (see description above). For example:

```
qstat -i
host1:

```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Req'd S	Elap Time
44[ ].host1	user1	workq	STDIN	--	1	1	--	--	Q	--

## 10.1.8 Listing Hosts Assigned to Jobs

The “-n” option to `qstat` displays the hosts allocated to any running job at the (optionally specified) PBS server, in addition to the other information presented in the alternative display. The `exec_host` information is printed immediately below the job (see job 51 in the example below), and includes the host name and number of virtual processors assigned to the job (i.e. “south/0”, where “south” is the host name, followed by the virtual processor(s) assigned.). A text string of “-” is printed for non-running jobs. Notice the differences between the queued and running jobs in the example below:

```
qstat -n

```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Req'd S	Elap Time
16.south	user1	workq	aims14	--	--	1	--	0:01	H	--
--										
18.south	user1	workq	aims14	--	--	1	--	0:01	W	--
--										
51.south	barry	workq	airfoil	930	--	1	--	0:13	R	0:01
			south/0							
52.south	user1	workq	my_job	--	--	1	--	0:10	Q	--
--										

## 10.1.9 Displaying Job Comments

The “-s” option to `qstat` displays the job comments, in addition to the other information presented in the alternative display. The job comment is printed immediately below the job. By default the job comment is updated by the scheduler with the reason why a given job is not running, or when the job began executing. A text string of “--” is printed for jobs whose comment has not yet been set. The example below illustrates the different type of messages that may be displayed:

```
qstat -s
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Time	Req'd S	Elap Time
16.south	user1	workq	aims14	--	--	1	--	0:01	H	--
Job held by user1 on Wed Aug 22 13:06:11 2004										
18.south	user1	workq	aims14	--	--	1	--	0:01	W	--
Waiting on user requested start time										
51.south	barry	workq	airfoil	930	--	1	--	0:13	R	0:01
Job run on host south - started Thu Aug 23 at 10:56										
52.south	user1	workq	my_job	--	--	1	--	0:10	Q	--
Not Running: No available resources on nodes										
57.south	susan	workq	solver	--	--	2	--	0:20	Q	--
--										

## 10.1.10 Showing State of Job, Job Array or Subjob

The “-t” option to `qstat` will show the state of a job, a job array object, and all non-X subjobs.

The “-J” option to `qstat` will show only the state of job arrays.

The combination of “-J” and “-t” options to `qstat` will show only the state of subjobs.

For example:

```
qstat -t
```

Job ID	Name	User	Time Use	S	Queue
44[ ].host1	STDIN	user1	0	B	workq
44[1].host1	STDIN	user1	00:00:00	R	workq
44[2].host1	STDIN	user1	0	Q	workq
44[3].host1	STDIN	user1	0	Q	workq

```
qstat -J
```

Job ID	Name	User	Time Use	S	Queue
44[ ].host1	STDIN	user1	0	B	workq

```
$ qstat -Jt
```

Job ID	Name	User	Time Use	S	Queue
44[1].host1	STDIN	user1	00:00:00	R	workq
44[2].host1	STDIN	user1	0	Q	workq
44[3].host1	STDIN	user1	0	Q	workq

### 10.1.11 Printing Job Array Percentage Completed

The “-p” option to `qstat` prints the default display, with a column for Percentage Completed. For a job array, this is the number of subjobs completed and deleted, divided by the total number of subjobs. For example:

```
qstat -p
```

Job ID	Name	User	% done	S	Queue
44[ ].host1	STDIN	user1	40	B	workq

### 10.1.12 Viewing Job Start Time

There are two ways you can find the job’s start time. If the job is still running, you can do a `qstat -f` and look for the `stime` attribute. If the job has finished, you look in the accounting log for the `S` record for the job. For an array job, only the `S` record is available; array jobs do not have a value for the `stime` attribute.

### 10.1.13 Viewing Estimated Start Times For Jobs

You can view the estimated start times and vnodes of jobs using the `qstat` command. If you use the `-T` option to `qstat` when viewing job information, the *Elap Time* field is replaced with the *Est Start Time* field. Running jobs are shown above queued jobs. Running jobs are sorted by their `stime` attribute (start time).

Queued jobs whose estimated start times are unset (`estimated.start_time = unset`) are displayed after those with estimated start times, with estimated start time shown as a double dash (“--”). Queued jobs with estimated start times in the past are treated as if their estimated start times are unset.

Time displayed is local to the `qstat` command. Current week begins on Sunday.

If the estimated start time or vnode information is invisible to unprivileged users, no estimated start time or vnode information is available via `qstat`.

Example output:

```
qstat -T
```

Job ID	Username	Queue	Jobname	SessID	NDS	TSK	Memory	Req'd Time	Req'd S	Est Start Time
5.host1	user1	workq	foojob	12345	1	1	128mb	00:10	R	--
9.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	11:30
10.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	Tu 15
7.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	Jul
8.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	2010
11.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	>5yrs
13.host1	user1	workq	foojob	--	1	1	128mb	00:10	Q	--

If the start time for a job cannot be estimated, the start time is shown as a question mark (“?”).

### 10.1.13.1 Why Does Estimated Start Time Change?

The estimated start time for your job may change for the following reasons:

- Changes to the system, such as vnodes going down, or the administrator offlining vnodes
- A higher priority job coming into the system, or a shift in priority of the existing jobs

### 10.1.14 Viewing Job Status in Wide Format

The `-w qstat` option displays job status in wide format. The total width of the display is extended from 80 characters to 120 characters. The Job ID column can be up to 30 characters wide, while the Username, Queue, and Jobname column can be up to 15 characters wide. The SessID column can be up to eight characters wide, and the NDS column can be up to four characters wide.

You can use this option only with the `-a`, `-n`, or `-s qstat` options.

This option is different from the `-w` option used with `-f`.

### 10.1.15 Viewing Information for Finished and Moved Jobs

You can view information for finished and moved jobs in the same way as for queued and running jobs, as long as the job history is still being stored by PBS.

The `-x` option to the `qstat` command allows you to see information for all jobs, whether they are running, queued, finished or moved. This information is presented in standard format.

You can view the history for selected sets of jobs:

Linux:

```
qstat -fx `qselect -x -s "MF" `
```

Windows:

```
for /F "usebackq" %j in (`"%Program Files%\PBSPro\exec\bin\qselect" -x -s MF`)
do ("%Program Files%\PBS\exec\bin\qstat" -fx %j)
```

### 10.1.15.1 Getting Information on Jobs Moved to Another Server

If your job is running at another server, you can use the `qstat` command to see its status. If your site is using peer scheduling, your job may be moved to a server that is not your default server. In this case, to see information on your job, you can use any of the following methods:

- Use `qstat -x` to see information about all jobs, whether running, queued, finished, or moved; you can specify job IDs
- Give the job ID as an argument to `qstat`. If you use only “`qstat`”, your job will not appear to exist. For example: you submit a job to ServerA, and it returns the job ID as “123.ServerA”. Then 123.ServerA is moved to ServerB. In this case, use

```
qstat 123
```

or

```
qstat 123.ServerA
```

to get information about your job. ServerA will query ServerB for the information. To list all jobs at ServerB, you can use:

```
qstat @<server>B
```

If you use “`qstat`” without the job ID, the job will not appear to exist.

### 10.1.15.2 Job History In Standard Format

You can use the `-x` option to the `qstat` command to see information for finished, moved, queued, and running jobs, in standard format.

Usage:

```
qstat -x
```

Displays information for queued, running, finished, and moved jobs, in standard format.

```
qstat -x <job ID>
```

Displays information for a job, regardless of its state, in standard format.

Example 10-1: Showing finished and moved jobs with queued and running jobs:

```
qstat -x
```

Job id	Name	User	Time Use	S	Queue
101.server1	STDIN	user1	00:00:00	F	workq
102.server1	STDIN	user1	00:00:00	M	destq@server2
103.server1	STDIN	user1	00:00:00	R	workq
104.server1	STDIN	user1	00:00:00	Q	workq

To see status for jobs, job arrays and subjobs that are queued, running, finished, and moved, use `qstat -xt`.

To see status for job arrays that are queued, running, finished, or moved, use `qstat -xJ`.

When information for a moved job is displayed, the destination queue and server are shown as <queue>@<server>.

Example 10-2: `qstat -x` output for moved job: destination queue is `destq`, and destination server is `server2`.

Job id	Name	User	Time Use	S	Queue
-----	-----	-----	-----	---	-----
101.sequoia	STDIN	user1	00:00:00	F	workq
102.sequoia	STDIN	user1	00:00:00	M	destq@server2
103.sequoia	STDIN	user1	00:00:00	R	workq

Example 10-3: Viewing moved job:

- There are three servers with hostnames ServerA, ServerB, and ServerC
- User1 submits job 123 to ServerA.
- After some time, User1 moves the job to ServerB.
- After more time, the administrator moves the job to QueueC at ServerC.

This means:

- The `qstat` command will show `QueueC@ServerC` for job 123.

### 10.1.15.3 Job History In Alternate Format

You can use the `-H` option to the `qstat` command to see job history for finished or moved jobs in alternate format. This does not display running or queued jobs.

Usage:

`qstat -H`

Displays information for finished or moved jobs, in alternate format

`qstat -H <job ID>`

Displays information for that job in alternate format, whether or not it is finished or moved

`qstat -H <destination>`

Displays information for finished or moved jobs at that destination

Example 10-4: Job history in alternate format:

`qstat -H`

Job ID	Username	Queue	Jobname	SessID	NDS	TSK	Memory	Req'd Time	Req'd S	Elap Time
-----	-----	----	-----	-----	---	---	-----	-----	---	-----
101.S1	user1	workq	STDIN	5168	1	1	--	--	F	00:00
102.S1	user1	Q1@S2	STDIN	--	1	2	--	--	M	--

To see alternate-format status for jobs, job arrays and subjobs that are finished and moved, use `qstat -Ht`.

To see alternate-format status for job arrays that are finished or moved, use `qstat -HJ`.

The `-H` option is incompatible with the `-a`, `-i` and `-r` options.

### 10.1.16 Grouping Jobs and Sorting by ID

You can use the `-E` option to sort and group jobs in the output of `qstat`. The `-E` option groups jobs by server and displays each group by ascending ID. This option also improves `qstat` performance. The following table shows how the `-E` option affects the behavior of `qstat`:

**Table 10-1: How `-E` Option Affects `qstat` Output**

How <code>qstat</code> is Used	Result Without <code>-E</code>	Result With <code>-E</code>
<code>qstat</code> (no job ID specified)	Queries the default server and displays result	No change in behavior; same as without <code>-E</code> option
<code>qstat &lt;list of job IDs from single server&gt;</code>	Displays results in the order specified	Displays results in ascending ID order
<code>qstat &lt;job IDs at multiple servers&gt;</code>	Displays results in the order they are specified	Groups jobs by server. Displays each group in ascending order

### 10.1.17 Caveats for Job Information

- MoM periodically polls jobs for usage by the jobs running on her host, collects the results, and reports this to the server. When a job exits, she polls again to get the final tally of usage for that job.

For example, MoM polls the running jobs at times T1, T2, T4, T8, T16, T24, and so on.

The output shown by a `qstat` during the window of time between T8 and T16 shows the resource usage up to T8.

If the `qstat` is done at T17, the output shows usage up through T16. If the job ends at T20, the accounting log (and the final log message, and the email to you if "`qsub -me`" was used in job submission) contains usage through T20.

- The final report does not include the epilogue. The time required for the epilogue is treated as system overhead.
- The order in which jobs are displayed is undefined.

## 10.2 Checking Server Status

To see server information in default format:

```
qstat -B [<server> ...]
```

To see server information in long format:

```
qstat -B -f [-F json|dsv [-D <delimiter>]] [-w] [<server> ...]
```

### 10.2.1 Viewing Server Information in Default Format

The `-B` option to `qstat` displays the status of the specified PBS server. One line of output is generated for each server queried. The three letter abbreviations correspond to various job limits and counts as follows: Maximum, Total, Queued, Running, Held, Waiting, Transiting, and Exiting. The last column gives the status of the server itself: active, idle, or scheduling.

```
qstat -B
Server Max Tot Que Run Hld Wat Trn Ext Status

fast.domain 0 14 13 1 0 0 0 0 Active
```

## 10.2.2 Viewing Server Information in Long Format

You can see server status in JSON or delimiter-separated value formats; see [section 10.4, “Full Display Options for Job, Queue, and Server Status”](#), on page 186.

When querying jobs, servers, or queues, you can add the “-f” option to `qstat` to change the display to the *full* or *long* display. For example, the server status shown above can be expanded using “-f” as shown below:

```
qstat -Bf
Server: fast.mydomain.com
 server_state = Active
 scheduling = True
 total_jobs = 14
 state_count = Transit:0 Queued:13 Held:0 Waiting:0
 Running:1 Exiting:0
 managers = user1@fast.mydomain.com
 default_queue = workq
 log_events = 511
 mail_from = adm
 query_other_jobs = True
 resources_available.mem = 64mb
 resources_available.ncpus = 2
 resources_default.ncpus = 1
 resources_assigned.ncpus = 1
 resources_assigned.nodect = 1
 scheduler_iteration = 600
 pbs_version = PBSPro_2020.1.1.41640
```

## 10.3 Checking Queue Status

To view queue information in default format:

```
qstat -Q [<destination> ...]
```

To view queue information in alternate format:

```
qstat -q [-G | -M] [<destination> ...]
```

To view queue information in long format:

```
qstat -Q -f [-F json|dsv [-D <delimiter>]] [-w] [<destination> ...]
```

If you specify a destination identifier, it takes one of the following three forms:

```
<queue>
```

```
@<server>
```

```
<queue>@<server>
```

If you specify `<queue>`, the request is for status of that queue at the default server.

If you use the `@<server>` form, the request is for status of all queues at that server.

If you specify a full destination identifier, `<queue>@<server>`, the request is for status of the named *queue* at the named *server*.

### 10.3.1 Viewing Queue Information in Default Format

The “-Q” option to `qstat` displays the status of specified queues at the (optionally specified) PBS server. One line of output is generated for each queue queried.

```
qstat -Q
Queue Max Tot Ena Str Que Run Hld Wat Trn Ext Type

workq 0 10 yes yes 7 1 1 1 0 0 Execution
```

The columns show the following for each queue:

- Queue Queue name
- Max Maximum number of jobs allowed to run concurrently in the queue
- Tot Total number of jobs in the queue
- Ena Whether the queue is enabled or disabled
- Str Whether the queue is started or stopped
- Que Number of queued jobs
- Run Number of running jobs
- Hld Number of held jobs
- Wat Number of waiting jobs
- Trn Number of jobs being moved (transiting)
- Ext Number of exiting jobs
- Type Type of queue: execution or routing

### 10.3.2 Viewing Queue Information in Long Format

You can see queue information in JSON or delimiter-separated value formats; see [section 10.4, “Full Display Options for Job, Queue, and Server Status”](#), on page 186.

Use the long format to see the value for each queue attribute:

```
qstat -Qf
Queue: workq
 queue_type = Execution
 total_jobs = 10
 state_count = Transit:0 Queued:7 Held:1 Waiting:1
 Running:1 Exiting:0
 resources_assigned.ncpus = 1
 hasnodes = False
 enabled = True
 started = True
```

### 10.3.3 Displaying Queue Limits in Alternate Format

The “-q” option to `qstat` displays any limits set on the requested (or default) queues. Since PBS is shipped with no queue limits set, any visible limits will be site-specific. The limits are listed in the format shown below.

```
qstat -q
server: south

Queue Memory CPU Time Walltime Node Run Que Lm State

workq -- -- -- -- 1 8 -- E R
```

## 10.4 Full Display Options for Job, Queue, and Server Status

### -f [-w]

Full display. Job, queue or server attributes displayed one to a line.

Optional -w prints each attribute on one unbroken line. Feed characters are converted:

- Newline is converted to backslash concatenated with “n”: “\n”
- Form feed is converted to backslash concatenated with “f”: “\f”

This -w is independent of the -w job alternate output option.

### -F dsv [-D <delimiter>]

Prints output in delimiter-separated value format. The default delimiter is a pipe (“|”). You can specify a character or a string delimiter using the -D argument to the -F dsv option. For example, to use a comma as the delimiter:

```
qstat -f -F dsv -D,
```

If the delimiter itself appears in a value, it is escaped:

- On UNIX/Linux, the delimiter is escaped with a backslash (“\”).
- On Windows, the delimiter is escaped with a caret (“^”).

Feed characters are converted:

- Newline is converted to backslash concatenated with “n”: “\n”
- Form feed is converted to backslash concatenated with “f”: “\f”

A newline separates each job from the next. Using newline as the delimiter leads to undefined behavior.

Example of getting output in delimiter-separated value format:

```
qstat -f -F dsv
```

```
Job Id: 1.vbox|Job Name = STDIN|Job Owner = root@vbox|job state = Q|queue = workq|server =
vbox|Checkpoint = u|ctime = Fri Nov 11 17:57:05 2016|Error_Path = ...
```

**-F json**

Prints output in JSON format (<http://www.json.org/>).

Attribute output is preceded by timestamp, PBS version, and PBS server hostname.

Example:

```
qstat -f -F json

{
 "timestamp":1479277336,
 "pbs_version":"14.1",
 "pbs_server":"vbox",
 "Jobs":{
 "1.vbox":{
 "Job_Name":"STDIN",
 "Job_Owner":"root@vbox",
 "job_state":"Q",
 ...
 }
 }
}
```

**-G**

Show size in gigabytes. Alternate format is used.

**-M**

Show size in megawords. A word is considered to be 8 bytes. Alternate format is used.

## 10.4.1 Caveats for the `qstat` Command

When you use the `-f` option to `qstat` to display attributes of jobs, queues, or servers, attributes that are unset may not be displayed. If you do not see an attribute, it is unset.

## 10.5 Selecting a List of Jobs

The `qselect` command provides a method to list the job identifier of those jobs, job arrays or subjobs which meet a list of selection criteria. Jobs are selected from those owned by a single server. The `qselect` command writes to standard output a list of zero or more job identifiers which meet the criteria specified by the options. Each option acts as a filter restricting the number of jobs which might be listed. With no options, the `qselect` command will list all jobs at the server which you are authorized to list (query status of). The `-u` option may be used to limit the selection to jobs owned by you or other specified users.

For a description of the `qselect` command, see [“qselect” on page 186 of the PBS Professional Reference Guide](#).

For example, say you want to list all jobs owned by user “barry” that requested more than 16 CPUs. You could use the following `qselect` command syntax:

```
qselect -u barry -l ncpus.gt.16
121.south
133.south
154.south
```

Notice that what is returned is the job identifiers of jobs that match the selection criteria. This may or may not be enough information for your purposes. Many users will use shell syntax to pass the list of job identifiers directly into `qstat` for viewing purposes, as shown in the next example (necessarily different between Linux and Windows).

Linux:

```
qstat -a `qselect -u barry -l ncpus.gt.16`
```

Job ID	User	Queue	Jobname	Sess	NDS	TSK	Mem	Req'd Time	Req'd S	Elap Time
121.south	barry	workq	airfoil	--	--	32	--	0:01	H	--
133.south	barry	workq	trialx	--	--	20	--	0:01	W	--
154.south	barry	workq	airfoil	930	--	32	--	1:30	R	0:32

Windows (type the following at the cmd prompt, all on one line):

```
for /F "usebackq" %j in (`qselect -u barry -l ncpus.gt.16`) do
(qstat -a %j)
121.south
133.south
154.south
```

Note: This technique of using the output of the `qselect` command as input to `qstat` can also be used to supply input to other PBS commands as well.

## 10.5.1 Listing Job Identifiers of Finished and Moved Jobs

You can list identifiers of finished and moved jobs in the same way as for queued and running jobs, as long as the job history is still being preserved.

The `-x` option to the `qselect` command allows you to list job identifiers for all jobs, whether they are running, queued, finished or moved. The `-H` option to the `qselect` command allows you to list job identifiers for finished or moved jobs only.

## 10.5.2 Listing Jobs by Time Attributes

You can use the `qselect` command to list queued, running, finished and moved jobs, job arrays, and subjobs according to their time attributes. The `-t` option to the `qselect` command allows you to specify how you want to select based on time attributes. You can also use the `-t` option twice to bracket a time period.

Example 10-5: Select jobs with end time between noon and 3PM.

```
qselect -te.gt.09251200 -te.lt.09251500
```

Example 10-6: Select finished and moved jobs with start time between noon and 3PM.

```
qselect -x -s "MF" -ts.gt.09251200 -ts.lt.09251500
```

Example 10-7: Select all jobs with creation time between noon and 3PM

```
qselect -x -tc.gt.09251200 -tc.lt.09251500
```

Example 10-8: Select all jobs including finished and moved jobs with `qtime` of 2.30PM (default relation is `.eq.`)

```
qselect -x -tq09251430
```

---

## 10.6 Checking License Availability

You can check to see where licenses are available. You can do either of the following:

- Display license information for the current host:
- Display resources available (including licenses) on all hosts:

```
qstat -Bf
```

```
qmgr
```

```
Qmgr: print node @default
```

If your site is using floating licenses, when looking at the server's `license_count` attribute, use the sum of the *Avail\_Global* and *Avail\_Local* values.

# Submitting Cray Jobs

## 11.1 PBS Jobs on Cray Shasta

Submitting a PBS job on a Shasta system is exactly like submitting a job on a standard Linux machine. The rest of this chapter does NOT apply to Shasta systems.

## 11.2 PBS Jobs on the Cray XC

You can submit jobs that are designed to run on the Cray XC, using the PBS select and place syntax.

When you submit a job that is designed to run on the Cray XC, you create a job script that contains the same `aprun` command as a non-PBS job, but submit the job using the PBS select and place syntax.

If a job does not request a login node, one is chosen for it. A login node is assigned to each PBS job that runs on the Cray XC. The job script runs on this login node.

Jobs requesting a `vntype` of `cray_compute` are expected to have an `aprun` in the job script to launch the job on the compute nodes. PBS does not verify that the job script contains an `aprun` statement.

You may find it helpful to run `qsub` in the foreground by using the `-f` option. This can avoid stale ALPS reservations not being released.

## 11.3 Resources for Cray XC

accelerator  
accelerator\_memory  
accelerator\_model  
energy  
eoe  
naccelerators  
PBScrayhost  
PBScraylabel\_<label name>  
PBScraynid  
PBScrayorder  
vntype

See [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#).

### 11.3.1 Resource Accounting for Cray XC

Jobs that request only compute nodes are not assigned resources from login nodes. PBS accounting logs do not show any login node resources being used by these jobs.

Jobs that request login nodes are assigned resources from login nodes, and those resources appear in the PBS accounting logs for these jobs.

PBS performs resource accounting on the login nodes, under the control of their MoMs.

Comprehensive System Accounting (CSA) runs on the compute nodes, under the control of the Cray XC system. CSA requires CLE 5.2.

## 11.4 Rules for Submitting Jobs on the Cray XC

### 11.4.1 Always Specify Node Type on Cray XC

If you want your job to run on Cray XC nodes, you must specify a Cray XC node type for your job. You do this by requesting a value for the `vntype` vnode resource. On each vnode on a Cray XC, the `vntype` resource includes one of the following values:

`cray_login`, for a login node

`cray_compute`, for a compute node

Each chunk of a Cray XC job that must run on a login node must request a `vntype` of `cray_login`.

Each chunk of a Cray XC job that must run on a compute node must request a `vntype` of `cray_compute`.

Example 11-1: Request any login node, and two compute-node vnodes. The job is run on the login node selected by the scheduler:

```
qsub -lselect=1:ncpus=2:vntype=cray_login +2:ncpus=2:vntype=cray_compute
```

Example 11-2: Launch a job on a particular login node by specifying the login node vnode name first in the select line. The job script runs on the specified login node:

```
qsub -lselect=1:ncpus=2:vnode=login1 +2:ncpus=2:vntype=cray_compute
```

For a description of the `vntype` resource, see [“Resources Built Into PBS” on page 265 of the PBS Professional Reference Guide](#).

### 11.4.2 Always Reserve Required Vnodes on Cray XC

Always reserve at least as many PEs as you request in your `aprun` statement.

### 11.4.3 Requesting Cray XC Login Node Where Job Script Runs

If you request a login node as part of your resource request, the login node resource request must be the first element of the select statement. The job script is run on the login node. If you request more than one login node, the job script runs on the first login node requested.

### 11.4.4 Cray XC Login Nodes in PBS Reservations

If the jobs that are to run in a PBS reservation require a particular login node, you must do the following:

- The reservation must request the specific login node
- Each job that will run in the reservation must request the same login node that the reservation requested

## 11.4.5 Specifying Number of Chunks on Cray XC

You specify the number of chunks by prefixing each chunk request with an integer. If not specified, this integer defaults to 1. For example, to specify 4 chunks with 2 CPUs each, and 8 chunks with 1 CPU each:

```
qsub -lselect=4:ncpus=2+8:ncpus=1
```

You cannot request the nchunk resource.

If you request fewer chunks, the scheduling cycle is faster. See [section 11.9.5, “Request Fewer Chunks on Cray XC”, on page 198](#).

## 11.4.6 Specify Host for Interactive Jobs on Cray XC

Interactive jobs on a Cray XC must run on a login node. When you run an interactive job, specify the login node as the host for the job. You can do so using a PBS directive, or the command line. For example:

```
qsub -l select=host=<name of login node> -I job.sh
#PBS -l select=host=<name of login node>
```

See [section 6.11, “Running Your Job Interactively”, on page 121](#).

# 11.5 Techniques for Submitting Cray XC Jobs

## 11.5.1 Requesting Groups of Cray XC Login Nodes

If you want to use groups of esLogin nodes and internal login nodes, your administrator can set the vntype resource on these nodes to a special value, for example *cray\_compile*.

To submit a job requesting any combination of esLogin nodes and internal login nodes, you specify the special value for the vntype resource in your select statement. For example:

```
qsub -lselect=4:ncpus=1:vntype=cray_compile job
```

## 11.5.2 Using Internal Cray XC Login Nodes Only

Compiling, preprocessing, and postprocessing jobs can run on internal login nodes. Internal login nodes have a vntype value of *cray\_login*. If you want to run a job that needs to use the resources on internal login nodes only, you can specify vntype=cray\_login in your select statement. For example:

```
qsub -lselect=4:ncpus=1:vntype=cray_login job
```

## 11.5.3 Using Cray XC Compute Nodes

If your job script contains an aprun launch, you must run your job on compute nodes. To run your job on compute nodes, specify a vntype of *cray\_compute*. For example:

```
lselect=2:ncpus=2:vntype=cray_compute
```

## 11.5.4 Requesting Specific Groups of Cray XC Nodes

You can use select and place to request the groups of vnodes you want.

You may need to group nodes by some criteria, for example:

- Certain nodes are fast nodes
- Certain nodes share a required or useful characteristic
- Some combination of nodes gives the best performance for an application

Your administrator can set up either of the following:

- Custom Boolean resources on each vnode, which reflect how the nodes are labeled, and allow you to request the vnodes that represent the group of nodes you want. These resources are named *PBScraylabel\_<label name>*, and set to *True* on the vnodes that represent the labeled nodes.

Your administrator must label the groups of nodes. For example, if a node is both fast and best for App1, it can have two labels, *fast*, and *BestForApp1*.

To request the fast nodes in this example, add the following to each chunk request:

```
:PBScraylabel_fast=True
```

- Other custom resources on each vnode, which are set to reflect the vnode's characteristics. For example, if a vnode is fast, it can have a custom string resource called "*speed*", with a value of *fast* on that vnode. You must ask your administrator for the name and possible values for the resource.

## 11.5.5 Requesting Cray XC Nodes in Specific Order

Your application may perform better when the ranks are laid out on specific nodes in a specific order. If you want to request vnodes so that the nodes are in a specific order, you can specify the host for each chunk of the job. For example, if you need nodes ordered "nid0, nid2, nid4", you can request the following:

```
qsub -l select=2:ncpus=2:host=nid0 +2:ncpus=2:host=nid2 +2:ncpus=2:host=nid4
```

## 11.5.6 Requesting Specific Hardware on Cray XC

PBS allows you to specifically request (or avoid) specific hardware. Your administrator must create a Boolean resource on each vnode, and set it to *True* where the vnode has that specific hardware. We recommend that the Boolean is called "*PBScraylabel\_<hardware name>*".

You request or avoid this resource using *PBScraylabel\_<hardware name>=True* or *PBScraylabel\_<hardware name>=False*. For example:

```
qsub -lselect=3:ncpus=2:PBScraylabel_new_and_fast=true myjob
```

## 11.5.7 Requesting Accelerators on Cray XC

Accelerators are associated with vnodes when those vnodes represent a host that has at least one accelerator in state *UP*. PBS allows you to request vnodes with associated accelerators. PBS sets the value of the *naccelerators* host-level resource to the number of accelerators on the host. Note that this value is set for all vnodes on that host, so if you have a host with one accelerator and four vnodes, each of the four vnodes has *naccelerators* set to 1.

To request accelerators for your job, use the integer *naccelerators* resource to request a specific number of accelerators, or the Boolean *accelerator* resource if you do not care how many accelerators you get.

To request a vnode on a host with a specific number of associated accelerators, include the following in the job's select statement:

```
naccelerators = <number of accelerators>
```

To request a vnode on a host with any number of associated accelerators, you can include the following in the job's select statement:

```
accelerator = True
```

### 11.5.7.1 Advice on Requesting Accelerators on Cray XC

- When requesting accelerators, put them in the same chunks as CPUs. Otherwise the accelerators could end up in a chunk taken from a different host from the CPUs, and in that case your CPUs could be on a host without an accelerator.
- Use `accelerator=True` in a chunk only when you don't care how many accelerators are in the chunk.

### 11.5.7.2 Examples of Requesting Accelerators on Cray XC

Example 11-3: You want a total of 40 PEs with 4 PEs per compute node and one accelerator per compute node:

```
-lselect=10:ncpus=4:naccelerators=1
```

Example 11-4: You want 30 PEs and a Tesla\_x2090 accelerator on each host, and the accelerator should have at least 4000MB, and you don't care how many hosts the job uses:

```
-lselect=30:ncpus=1:naccelerators=1:accelerator_model="Tesla_x2090" :accelerator_memory=4000MB
myjob
```

Example 11-5: You want a total of 40 PEs with 4 PEs per compute node and at least one accelerator per compute node:

```
-lselect=10:ncpus=4:accelerator=True
```

Example 11-6: Your system has some compute nodes with one type of accelerator (GPU1), and another type of compute node with a different type of accelerator (GPU2), and you want to request 10 PEs and 1 accelerator of model "GPU1" per compute node and 4 PEs and 1 accelerator of model "GPU2" per compute node. Your job request would look like this:

```
-lselect=10:ncpus=1:naccelerators=1:accelerator_model="GPU1"
+4:ncpus=1:naccelerators=1:accelerator_model="GPU2" myjob
```

## 11.6 Using Xeon Phi Vnodes on Cray XC

PBS automatically detects a Xeon Phi in the ALPS inventory. The Xeon Phi attributes are configured automatically in the PBS vnode attributes. A job can make an explicit request for a Xeon Phi on a compute node and be dispatched to that node.

When using Xeon Phi vnodes, it's generally useful to request an AOE that gives you a Xeon Phi memory model with your desired values for `numa_cfg` and `hbm_cache_pct`. Run the `pbsnodes` command to find the available AOE's (look at `resources_available.aoe`) and choose the AOE you want.

To request Xeon Phi vnodes for the compute nodes used by your job, specify the `cray_compute` resource. For example, to request 10 Xeon Phi vnodes:

```
qsub -l select=10:vntype=cray_compute:aoe=<desired AOE>
```

## 11.7 Using Hyperthreads on Cray XC

PBS supports hyperthreading on Cray X\* series systems using ALPS. On each vnode, PBS sets `resources_available.ncpus` to the number of compute unit elements returned in the XML inventory. This allows PBS to make ALPS reservations for the compute units of a node, and get all of the hyperthreads associated with those compute units.

You can use `aprun -j` to control how you use hyperthreads on XC series machines.

Your administrator may label hyperthreaded vnodes with a custom resource.

We recommend that when you submit jobs to PBS, you use the size of a compute node as the size of a chunk.

To use hyperthreading in your job, request hyperthreading in your `aprun` call in your job script. Please refer to Cray's man page for `aprun`.

Check the *Cray Programming Environment User Guide* for Cray's advice on using CPUs and compute units.

When hyperthreading is enabled on a system, each core is paired with one associated hyperthread, and you should request `ncpus` in multiples of 2 so that each associated hyperthread is assigned to the job's cgroup.

When hyperthreading is not enabled, you should request just the cores.

Let's say you request the following:

```
select=1:ncpus=2
```

If hyperthreading is enabled, this nets one core and one hyperthread.

If hyperthreading is not enabled, this nets two cores.

## 11.8 Viewing Cray XC Job Information

### 11.8.1 Finding Out Where Job Was Launched on Cray XC

To determine the internal login node where the job was launched, use the `qstat -f` command:

```
qstat -f <job ID>
```

Look at the `exec_host` line of the output. The first vnode is the login node where the job was launched.

### 11.8.2 Listing Jobs Running on Vnode on Cray XC

To see which jobs are running on a vnode, use the `pbsnodes` command:

```
pbsnodes -av
```

The `jobs` attribute of each vnode lists the jobs running on that vnode.

Jobs launched from an internal login node, requesting a `vntype` of `cray_compute` only, are **not** listed in the internal login node's vnode's `jobs` attribute.

Jobs that are actually running on a login node, which requested a `vntype` of `cray_login`, do appear in the login node's vnode's `jobs` attribute.

## 11.8.3 How ALPS Request Is Constructed on Cray XC

The reservation request that is sent to the Cray XC is constructed from the contents of the `exec_vnode` and `Resource_List.select` job attributes. If the `exec_vnode` attribute contains chunks asking for the same `ncpus` and `mem`, these are grouped into one section of an ALPS request. Cray XC requires one CPU per thread. The ALPS request is constructed using the following rules:

**Table 11-1: How Cray XC Elements Are Derived From `exec_vnode` Terms**

Cray XC Element	<code>exec_vnode</code> Term
Processing Element (PE)	<code>mpiprocs</code>
Requested number of PEs / compute node in this section of job request (width)	Total <code>mpiprocs</code> on vnodes representing compute node involved in this section of job request
Number of threads per PE (depth)	(total assigned <code>ncpus</code> on vnodes representing a compute node) / (total <code>mpiprocs</code> on vnodes representing a compute node)
Memory per PE ( <code>mem</code> )	(total memory in chunk request)/total <code>mpiprocs</code> in chunk
Number of PEs per compute node ( <code>nppn</code> )	Sum of <code>mpiprocs</code> on vnodes representing a compute node
Number of PEs per segment ( <code>npps</code> )	Not used.
Number of segments per node ( <code>nspn</code> )	Not used.
NUMA node (segments)	Not used.

## 11.8.4 Viewing Accelerator Information on Cray XC

There is no `aprun` interface for requesting accelerator memory or model, so this information is not translated into Cray XC elements. To see this information, look in the MoM logs for the job's login node.

## 11.9 Caveats and Advice for Cray XC

### 11.9.1 Using Combination or Number Resources on Cray XC

When requesting a resource that is set up by the administrator, you **must** use the same resource string values as the ones set up by the administrator. “012” is **not** the same as “102” or “201”.

### 11.9.2 Avoid Invalid Cray XC Requests

It is possible to create a `select` and `place` statement that meets the requirements of PBS but not of the Cray XC.

Example 11-7: The Cray XC `width` and `depth` values cannot be calculated from `ncpus` and `mpiprocs` values. For example, if `ncpus` is 2 and `mpiprocs` is 4, the `depth` value is calculated by dividing `ncpus` by `mpiprocs`, and is one-half. This is not a valid `depth` value for Cray XC.

Example 11-8: ALPS cannot run jobs with some complex `select` statements. In particular, a multiple program, multiple data (MPMD) ALPS reservation where two groups span a compute node will produce an ALPS error, because the `nid` shows up in two `ReserveParam` sections.

## 11.9.3 Resource Restrictions and Deprecations on Cray XC

### 11.9.3.1 mpp\* Resources Removed

The mpp\* resources are no longer used.

## 11.9.4 Do Not Request PBScrayorder on Cray XC

Do not use PBScrayorder in a resource request.

## 11.9.5 Request Fewer Chunks on Cray XC

The more chunks in each translated job request, the longer the scheduling cycle takes. Jobs that request a value for ncpus effectively direct PBS to use the size of ncpus as the value for ncpus for each chunk, thus dividing the number of chunks by ncpus.

If you are on a homogeneous system, we recommend that chunks use the value for ncpus for a vnode or for a compute node.

Example 11-9: Comparison of larger vs. smaller chunk size and the effect on scheduling time:

Submit job with chunk size 1 and 8544 chunks:

```
qsub -lselect=8544:ncpus=1 job
```

Job's Resource\_List:

```
Resource_List.ncpus = 8544
```

```
Resource_List.place = free
```

```
Resource_List.select = 8544:vntype=cray_compute
```

```
Submit_arguments = -lselect=8544:ncpus=1 job
```

Scheduling took 6 seconds:

```
12/05/2011 16:46:10;0080;pbs_sched;Job;23.example;considering job to run
```

```
12/05/2011 16:46:16;0040;pbs_sched;Job;23.example;Job run
```

If you are on a heterogeneous system, with varying sizes for vnodes or compute nodes, you can request chunk sizes that fit available hardware, but this may not be feasible.

## 11.9.6 Improving Performance on Cray XC

- You can speed performance via the -E option to qstat; see [section 10.1.16, “Grouping Jobs and Sorting by ID”, on page 183](#).
- We give several recommendations for improving file transfer performance in [section 14.6.6, “Advice on Improving File Transfer Performance”, on page 554 of the PBS Professional Administrator’s Guide](#).
- You can avoid using the -f option to qsub where possible; see [section 2.5.9, “Running qsub in the Foreground”, on page 30](#) and [“Options to qsub” on page 218 of the PBS Professional Reference Guide](#).

---

## 11.10 Errors and Logging on Cray XC

### 11.10.1 Invalid Cray XC Requests

When a select statement does not meet Cray XC requirements, and the Cray XC reservation fails, the following error message is printed in MoM's log, at log event class 0x080:

`"Fatal MPP reservation error preparing request"`

### 11.10.2 Job Requests More Than Available on Cray XC

If `do_not_span_psets` is set to `True`, and a job requests more resources than are available in one placement set, the following happens:

- The job's comment is set to the following:  
`"Not Running: can't fit in the largest placement set, and can't span psets"`
- The following message is printed to the scheduler's log:  
`"Can't fit in the largest placement set, and can't span placement sets"`

# 12

# Using Provisioning

PBS provides automatic provisioning of an OS or application on vnodes that are configured to be provisioned. When a job requires an OS that is available but not running, or an application that is not installed, PBS provisions the vnode with that OS or application.

## 12.1 Definitions

### **AOE**

The environment on a vnode. This may be one that results from provisioning that vnode, or one that is already in place

### **Provision**

To install an OS or application, or to run a script which performs installation and/or setup

### **Provisioned Vnode**

A vnode which, through the process of provisioning, has an OS or application that was installed, or which has had a script run on it

## 12.2 How Provisioning Works

Provisioning can be performed only on vnodes that have provisioning enabled, shown in the vnode's `provision_enable` attribute.

Provisioning can be the following:

- Directly installing an OS or application
- Running a script which may perform setup or installation

Each vnode is individually configured for provisioning with a list of available AOE's, in the vnode's `resources_available.aoe` attribute.

Each vnode's `current_aoe` attribute shows that vnode's current AOE. The scheduler queries each vnode's `aoe` resource and `current_aoe` attribute in order to determine which vnodes to provision for each job.

Provisioning can be used for interactive jobs.

A job's `walltime` clock starts when provisioning for the job has finished.

### 12.2.1 Causing Vnodes To Be Provisioned

An AOE can be requested for a job or a reservation. When a job requests an AOE, that means that the job will be run on vnodes running that AOE. When a reservation requests an AOE, that means that the reservation reserves vnodes that have that AOE available. The AOE is instantiated on reserved vnodes only when a job requesting that AOE runs.

When the scheduler runs each job that requests an AOE, it either finds the vnodes that satisfy the job's requirements, or provisions the required vnodes. For example, if SLES is available on a set of vnodes that otherwise suit your job, you can request SLES for your job, and regardless of the OS running on those vnodes before your job starts, SLES will be running at the time the job begins execution.

## 12.2.2 Using an AOE

When you request an AOE for a job, the requested AOE must be one of the AOE's that has been configured at your site. For example, if the AOE's available on vnodes are “*rhel*” and “*sles*”, you can request only those; you cannot request “*suse*”.

Your job can run where its requested AOE can be supplied both by provisioning and where the AOE already matches the request. Some of your job chunks can run on the non-provisionable vnodes that already match the requested AOE, and some chunks can run on vnodes that can be provisioned to match the requested AOE.

You can request a reservation for vnodes that have a specific AOE available. This way, jobs needing that AOE can be submitted to that reservation. This means that jobs needing that AOE are guaranteed to be running on vnodes that have that AOE available.

Each reservation can have at most one AOE specified for it. Any jobs that run in that reservation must not request a different AOE from the one requested for the reservation. That is, the job can run in the reservation if it either requests no AOE, or requests the same AOE as the reservation.

## 12.2.3 Job Substates and Provisioning

When a job is in the process of provisioning, its substate is *provisioning*. This is the description of the substate:

*provisioning*

The job is waiting for vnode(s) to be provisioned with its requested AOE. Integer value is 71. See [“Job Substates” on page 362 of the PBS Professional Reference Guide](#) for a list of job substates.

The following table shows how provisioning events affect job states and substates:

**Table 12-1: Provisioning Events and Job States/Substates**

Event	Initial Job State, Substate	Resulting Job State, Substate
Job submitted		<i>Queued and ready for selection</i>
Provisioning starts	<i>Queued, Queued</i>	<i>Running, Provisioning</i>
Provisioning fails to start	<i>Queued, Queued</i>	<i>Held, Held</i>
Provisioning fails	<i>Running, Provisioning</i>	<i>Queued, Queued</i>
Provisioning succeeds and job runs	<i>Running, Provisioning</i>	<i>Running, Running</i>
Internal error occurs	<i>Running, Provisioning</i>	<i>Held, Held</i>

## 12.3 Requirements and Restrictions

### 12.3.1 Host Restrictions

#### 12.3.1.1 Single-vnode Hosts Only

PBS will provision only single-vnode hosts. Do not attempt to use provisioning on hosts that have more than one vnode.

### 12.3.1.2 Server Host Cannot Be Provisioned

The server host cannot be provisioned: a MoM can run on the server host, but that MoM's vnode cannot be provisioned. The `provision_enable` vnode attribute, `resources_available.aoe`, and `current_aoe` cannot be set on the server host.

## 12.3.2 AOE Restrictions

Only one AOE can be instantiated at a time on a vnode.

Only one kind of `aoe` resource can be requested in a job. For example, an acceptable job could make the following request:

```
-l select=1:ncpus=1:aoe=suse+1:ncpus=2:aoe=suse
```

### 12.3.2.1 Vnode Job Restrictions

A vnode with any of the following jobs will not be selected for provisioning:

- One or more running jobs
- A suspended job
- A job being backfilled around

### 12.3.2.2 Provisioning Job Restrictions

A job that requests an AOE will not be backfilled around.

### 12.3.2.3 Vnode Reservation Restrictions

A vnode will not be selected for provisioning for job MyJob if the vnode has a confirmed reservation, and the start time of the reservation is before job MyJob will end.

A vnode will not be selected for provisioning for a job in reservation R1 if the vnode has a confirmed reservation R2, and an occurrence of R1 and an occurrence of R2 overlap in time and share a vnode for which different AOE's are requested by the two occurrences.

## 12.3.3 Requirements for Jobs

### 12.3.3.1 If AOE is Requested, All Chunks Must Use Same AOE

If any chunk of a job requests an AOE, all chunks must use that AOE, even if they do not explicitly request an AOE. For example, if your job requests

```
-l select=2:ncpus=1:aoe=suse+4:ncpus=2
```

all chunks must use the `suse` AOE.

If a job requesting an AOE is submitted to a reservation, that reservation must also request the same AOE.

## 12.4 Using Provisioning

### 12.4.1 Requesting Provisioning

You request a reservation with an AOE in order to reserve the resources and AOE required to run a job. You request an AOE for a job if that job requires that AOE. You request provisioning for a job or reservation using the same syntax.

You can request an AOE for the entire job/reservation:

```
-l aoe = <AOE>
```

Example:

```
-l aoe = suse
```

The `-l <AOE>` form cannot be used with `-l select`.

You can request an AOE for a single-chunk job/reservation:

```
-l select=<chunk request>:aoe=<AOE>
```

Example:

```
-ls select=1:ncpus=2:aoe=rhel
```

You can request the same AOE for each chunk of a job/reservation:

```
-l select=<chunk request>:aoe=<AOE> + <chunk request>:aoe=<AOE>
```

Example:

```
-l select=1:ncpus=1:aoe=suse + 2:ncpus=2:aoe=suse
```

You can request the an AOE for some, but not all, chunks of a job/reservation:

```
-l select=<chunk request>:aoe=<AOE> + <chunk request>
```

Example:

```
-l select=1:ncpus=1:aoe=suse + 2:ncpus=2
```

### 12.4.2 Commands and Provisioning

If you try to use PBS commands on a job that is in the *provisioning* substate, the commands behave differently. The provisioning of vnodes is not affected by the commands; if provisioning has already started, it will continue. The following table lists the affected commands:

**Table 12-2: Effect of Commands on Jobs in Provisioning Substate**

Command	Behavior While in Provisioning Substate
qdel	(Without force) Job is not deleted
	(With force) Job is deleted
qsig -s suspend	Job is not suspended
qhold	Job is not held
qrerun	Job is not queued

**Table 12-2: Effect of Commands on Jobs in Provisioning Substate**

Command	Behavior While in Provisioning Substate
qmove	Cannot be used on a job that is provisioning
qalter	Cannot be used on a job that is provisioning
qrun	Cannot be used on a job that is provisioning

### 12.4.3 How Provisioning Affects Jobs

A job that has requested an AOE will not preempt another job. Therefore no job will be terminated in order to run a job with a requested AOE.

A job that has requested an AOE will not be backfilled around.

## 12.5 Caveats and Errors

### 12.5.1 Requested Job AOE and Reservation AOE Should Match

Do not submit jobs that request an AOE to a reservation that does not request the same AOE. Reserved vnodes may not supply that AOE; your job will not run.

### 12.5.2 Allow Enough Time in Reservations

If a job is submitted to a reservation with a duration close to the walltime of the job, provisioning could cause the job to be terminated before it finishes running, or to be prevented from starting. If a reservation is designed to take jobs requesting an AOE, leave enough extra time in the reservation for provisioning.

### 12.5.3 Requesting Multiple AOE's For a Job or Reservation

Do not request more than one AOE per job or reservation. The job will not run, or the reservation will remain unconfirmed.

### 12.5.4 Held and Requeued Jobs

The job is held with a system hold for the following reasons:

- Provisioning fails due to invalid provisioning request or to internal system error
- After provisioning, the AOE reported by the vnode does not match the AOE requested by the job

The hold can be released by the PBS Administrator after investigating what went wrong and correcting the mistake.

The job is requeued for the following reasons:

- The provisioning hook fails due to timeout
- The vnode is not reported back up

### 12.5.5 Conflicting Resource Requests

The values of the resources `arch` and `vnode` may be changed by provisioning. Do not request an AOE and either `arch` or `vnode` for the same job.

### 12.5.6 Job Submission and Alteration Have Same Requirements

Whether you use the `qsub` command to submit a job, or the `qalter` command to alter a job, the job must eventually meet the same requirements. You cannot submit a job that meets the requirements, then alter it so that it does not.

# 13

## Using Accounting

### 13.1 Using Accounting

#### 13.1.1 Specifying Accounting String

You can associate an accounting string with your job by setting the value of the `Account_Name` job attribute. This attribute has no default value. You can set the value of `Account_Name` at the command line or in a PBS directive:

```
qsub -A <accounting string>
#PBS Account_Name=<accounting string>
```

The *<accounting string>* can be any string of characters; PBS does not attempt to interpret it.

You can use the `qalter` command to change the value of the `Account_Name` job attribute while the job is queued, but not while the job is running.

#### 13.1.2 Using Comprehensive System Accounting

You can use CSA on Cray systems running CLE 5.2. PBS support for CSA on HPE systems is no longer available. The CSA functionality for HPE systems has been **removed** from PBS.

CSA provides accounting information about user jobs, called user job accounting.

CSA works the same with and without PBS. To run user job accounting, either you must specify the file to which raw accounting information will be written, or an environment variable must be set. The environment variable is `ACCT_TMPDIR`. This is the directory where a temporary file of raw accounting data is written.

To run user job accounting, you issue the CSA command “`ja <filename>`” or, if the environment variable `ACCT_TMPDIR` is set, “`ja`”. In order to have an accounting report produced, you issue the command “`ja -<options>`” where the options specify that a report should be written and what kind to write. To end user job accounting, you issue the command “`ja -t`”; the `-t` option can be included in the previous set of options. See the man page on `ja` for details.

The starting and ending `ja` commands must be used before and after any other commands you wish to monitor. Here are examples of a command line and a script:

On the command line:

```
qsub -N myjobname -l ncpus=1
ja myrawfile
sleep 50
ja -c > myreport
ja -t myrawfile
ctrl-D
```

Accounting data for your job (sleep 50) is written to `myreport`.

If you create a job script `foo` with these commands:

```
#PBS -N myjobname
#PBS -l ncpus=1
ja myrawfile
sleep 50
ja -c > myreport
ja -t myrawfile
```

Then you can run your job script via `qsub`, to do the same thing as in the previous example:

```
qsub foo
```

### 13.1.3 Using Dependencies with Accounting

If you need to run end-of-day accounting, you can use dependencies; see [section 6.2, “Using Job Dependencies”, on page 107](#)

### 13.1.4 Advice and Caveats for Using Accounting

#### 13.1.4.1 Use an Integrated MPI

Many MPIs are integrated with PBS. PBS provides tools to integrate most of them; a few MPIs supply the integration. When a job is run under an integrated MPI, PBS can track resource usage, signal job processes, and perform accounting for all processes of the job.

When a job is run under an MPI that is not integrated with PBS, PBS is limited to managing the job only on the primary vnode, so resource tracking, job signaling, and accounting happen only for the processes on the primary vnode.

Under Windows, some MPIs such as MPICH are not integrated with PBS.

See [section 5.2.1, “Using an Integrated MPI”, on page 81](#).

# PBS Architecture

PBS is a distributed workload management system which manages and monitors the computational workload on a set of one or more computers.

## 2.1 PBS Components

You can manage one or more machines using PBS. PBS consists of commands, a data service, and the following daemons:

- Server daemon for central management; this daemon runs on Linux only.
- One or more scheduler daemons to schedule jobs; schedulers run on Linux only.
- Communication daemon to manage communication; this daemon also runs only on Linux.
- Job management daemon called MoM to manage each execution host; this daemon can run on Linux or Windows.

The data service runs on Linux only. Commands can run on Linux or Windows.

### 2.1.1 Single Execution System

If PBS is to manage a single system, all components are installed on that same system. For installation instructions, see the *PBS Professional Installation & Upgrade Guide*.

The following illustration shows how communication works when PBS is on a single host in TPP mode. For more on TPP mode, see [“Communication” on page 45 in the PBS Professional Installation & Upgrade Guide](#).

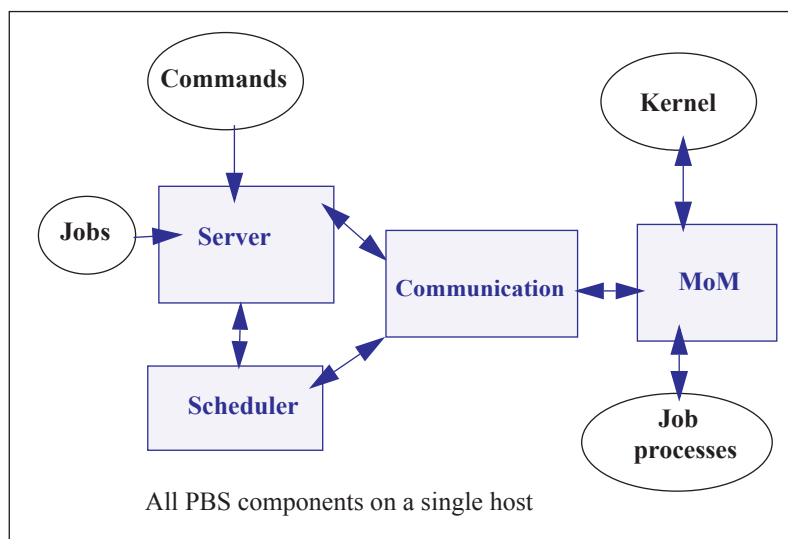

Figure 2-1: PBS daemons on a single execution host

## 2.1.2 Single Execution System with Front End

The PBS server and default scheduler (`pbs_server` and `pbs_sched`) can run on one system and jobs can execute on another. Job execution is managed by the MoM daemon. The following illustration shows how communication works when the PBS server and scheduler are on a front-end system and MoM is on a separate host, in TPP mode. For more on TPP mode, see [“Communication” on page 45 in the PBS Professional Installation & Upgrade Guide](#).

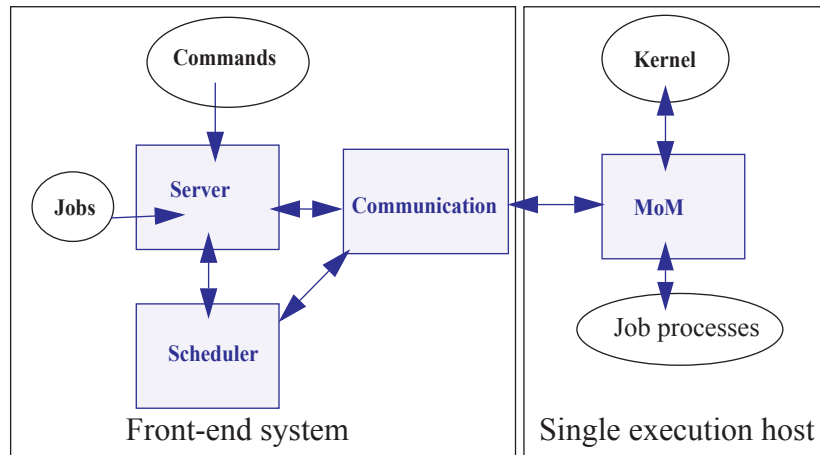

Figure 2-2: PBS daemons on single execution system with front end

### 2.1.3 Multiple Execution Systems

When you run PBS on several systems, normally the server (`pbs_server`), the scheduler (`pbs_sched`), and the communication daemon (`pbs_comm`) are installed on a “front end” system, and a MoM (`pbs_mom`) is installed and run on each execution host. The following diagram illustrates this for an eight-host complex in TPP mode.

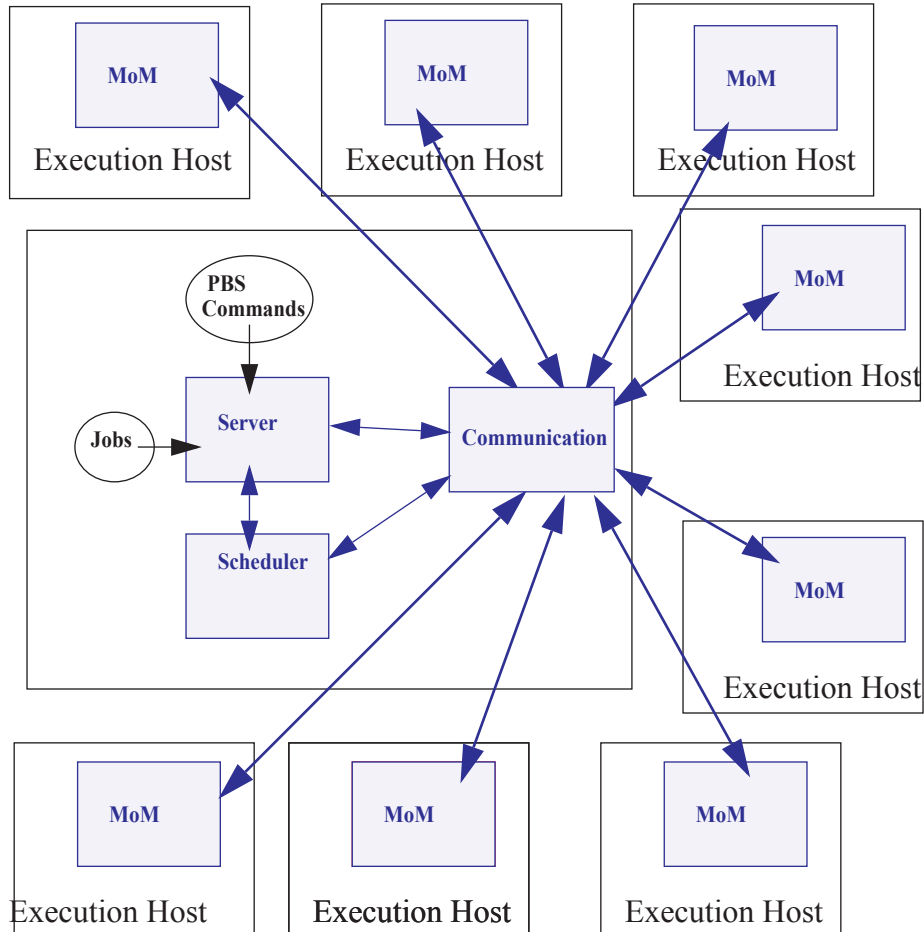

Figure 2-3: Typical PBS daemon locations for multiple execution hosts

### 2.1.4 Server

The *server* process is the central focus for PBS. In our documentation, it is generally referred to as *the server*; *the PBS server*; or by the execution name `pbs_server`. All commands and communication with the server are via an *Internet Protocol* (IP) network. The server provides core batch services such as receiving batch job requests, creating batch jobs, modifying jobs, protecting jobs against system crashes, and sending jobs to MoM for execution. One server manages each PBS complex.

## 2.1.5 Job Executor (MoM)

The *Job Executor* is the component that actually places the job into execution. This daemon, *pbs\_mom*, is informally called *MoM* as it is the mother of all executing jobs on that host. MoM places a job into execution when it receives a copy of the job from the server. MoM creates a new session that is as identical to a user login session as is possible. For example, if the user's login shell is `ssh`, then MoM creates a session in which `.login` is run as well as `.cshrc`. MoM also returns the job's output to the user. One MoM runs on each execution host (a host where PBS jobs execute).

## 2.1.6 Scheduler

The *scheduler*, *pbs\_sched*, implements the site's policy controlling when each job is run and on which resources. The scheduler queries the MoMs to get the state of system resources, and queries the server to for the list of waiting jobs. See ["About Schedulers" on page 89 in the PBS Professional Administrator's Guide](#).

## 2.1.7 Communication Daemon

The *communication daemon*, *pbs\_comm*, handles communication between the other PBS daemons. For a complete description, see [section 4.5, "Inter-daemon Communication Using TPP", on page 49](#).

## 2.1.8 Privilege

PBS recognizes separate roles and levels of privilege: Manager role is required for sensitive operations, Operator role can perform various less-sensitive functions, and User role allows access to only the user's own jobs. Root privilege is required for some of the Manager operations; the combination of root privilege and Manager role is called PBS Administrator. See ["Security" on page 359 in the PBS Professional Administrator's Guide](#).

## 2.1.9 Commands

PBS provides a set of commands for submitting and managing jobs, and for managing PBS. PBS commands are described in ["PBS Commands" on page 21 of the PBS Professional Reference Guide](#).

# Server Functions

## 3.1 Roles and Required Privilege

PBS recognizes specific roles and levels of privilege, and these are required for some operations on PBS. For details, see ["User Roles and Required Privilege" on page 359 in the PBS Professional Administrator's Guide](#).

## 3.2 Batch Server Functions

A batch server provides services in the following ways:

- The server provides a service at the request of a client. Clients are processes that make requests of a batch server. The requests may ask for an action to be performed on one or more jobs, one or more queues, the server itself, etc. Any requests that cannot be successfully completed are rejected. The reason for the rejection is returned in the reply to the client.
- The server provides a deferred service when it detects a change in conditions that it monitors. The server may, depending on conditions being monitored, defer a client service request until a later time. Deferred services include file staging, sending jobs for execution, etc. See [section 3.7, "Deferred Services", on page 12](#).

The server also performs a number of internal bookkeeping functions.

## 3.3 Server Management

The following sections describe the services provided by a batch server in response to a request from a client. The requests are grouped in the following subsections by the type of object affected by the request: server, queue, job, reservation, vnode, hook, or resource. The batch requests described in this section control the functioning of the batch server. The control is either direct as in the *Shut Down* request, or indirect as when server attributes are modified. For a list of batch request codes, see ["Request Codes" on page 395 of the PBS Professional Reference Guide](#).

### 3.3.1 Manage Request

The *Manage* request supports `qmgr` and other commands. For more information, see ["qmgr" on page 149 of the PBS Professional Reference Guide](#).

### 3.3.2 Server Status Request

The status of the server may be requested with a server *Status* request. The batch server will reject the request if the user of the client is not authorized to query the status of the server. If the request is accepted, the server will return a server *Status Reply*. See ["qstat" on page 197 of the PBS Professional Reference Guide](#) details of which server attributes are returned to the client.

### 3.3.3 Starting the PBS Server

A batch request to start a server cannot be sent to a server since the server is not running. Therefore a batch server must be started by a process local to the host on which the server is to run. For how to start the server, see [“Server: Starting, Stopping, Restarting” on page 163 in the PBS Professional Installation & Upgrade Guide](#).

The server recovers the state of managed objects, such as queues and jobs, from the information last recorded by the server. The treatment of jobs which were in the running state when the server previously shut down is dictated by the start up mode; see [“pbs\\_server” on page 108 of the PBS Professional Reference Guide](#).

### 3.3.4 Stopping the PBS Server

The batch server is "shut down" when it no longer responds to requests from clients and does not perform deferred services. The batch server is requested to shut down by sending it a server *Shutdown* request. The server will reject the request from a client not authorized to shut down the server. When the server accepts a shut down request, it will terminate in the manner described in [“qterm” on page 233 of the PBS Professional Reference Guide](#). When shutting down, the server must record the state of all managed objects (jobs, queues, etc.) in non-volatile memory. Jobs which were running will be marked in the secondary state field for possible special treatment when the server is restarted. If checkpoint is supported, any job running at the time of the shut down request whose Checkpoint attribute is not *n*, will be checkpointed. This includes jobs whose Checkpoint attribute value is “unspecified”, a value of *u*. If the server receives either a SIGTERM or a SIGSHUTDN signal, the server will act as if it had received a shut down immediate request.

## 3.4 Queue Management

The following client requests operate on the queues managed by the server.

### 3.4.1 Queue Status Request

The status of a queue at the server may be requested with a *Queue Status* request. The batch server requires that the following conditions are true:

- The user of the client is authorized to query the status of the designated queue
- The specified queue exists on the server

If the request does not specify a queue, status of all the queues at the server will be returned. When the request is accepted, the server will return a *Queue Status Reply*. See [“qstat” on page 197 of the PBS Professional Reference Guide](#) for details of which queue attributes are returned to the client.

## 3.5 Job Management

The following client requests operate on jobs managed by the server. These requests do not require any special privilege except when the job for which the request is issued is not owned by the user making the request.

### 3.5.1 Queue Job Request

A *Queue Job* request consists of several subrequests: *Initiate Job Transfer*, *Job Data*, *Job Script*, and *Commit*. The end result of a successful *Queue Job* request is an additional job being managed by the server. The job may have been created by the request or it may have been moved from another server. After the successful request, the job resides in a queue managed by the server. When a queue is not specified in the request, the job is placed in the default queue. The administrator can specify the default queue. We call the queue where the job ends up the *target queue*. The batch server requires that the following conditions are true:

- The client is authorized to create a job in the target queue
- The target queue exists at the server.
- The target queue is enabled.
- If the target queue is an execution queue, no resource requirement of the job exceeds the limits set for the queue
- If the target queue is an execution queue, all resources requested by the job are recognized
- The job requires access to a user identifier that the client is authorized to access

When a job is placed in an execution queue, it is put in the queued state unless one of the following conditions applies:

- The job has an *Execution\_Time* attribute that specifies a time in the future and the *Hold\_Types* attribute has value of *no hold*, in which case the job is placed in the waiting state
- The job has a *Hold\_Types* attribute with a value other than *no hold*, in which case the job is placed in the held state.

When a job is placed in a routing queue, its state may change based on the conditions described in [section 3.7.4, “Job Routing”, on page 15](#).

A server that accepts a *Queue Job* request for a new job will do the following:

- Add the *PBS\_O\_QUEUE* variable to the *Variable\_List* attribute of the job and set the value to the name of the target queue
- Add the *PBS\_JOBID* variable to the *Variable\_List* attribute of the job and set the value to the job identifier assigned to the job
- Add the *PBS\_JOBNAME* variable to the *Variable\_List* attribute of the job and set the value to the value of the *Job\_Name* attribute of the job

When the server accepts a *Queue Job* request for an existing job, the server will send a *Track Job* request to the server which created the job.

### 3.5.2 Job Credential Request

The *Job Credential* sub-request is part of the *Queue Job* request. This sub-request transfers a copy of the credential provided by the authentication facility explained below.

### 3.5.3 Job Script Request

The *Job Script* sub-request is part of the *Queue Job* request. This sub-request passes a block of the job script file to the receiving server. The script is broken into blocks to prevent having to hold the entire script in memory. Multiple *Job Script* sub-requests may be required to transfer the script file.

### 3.5.4 Commit Request

The *Commit* sub-request is part of the *Queue Job* request. The *Commit* notifies the receiving server that all parts of the job have been transferred and the receiving server should now assume ownership of the job. Prior to sending the *Commit*, the sending client, command, or another server, is the owner.

### 3.5.5 Message Job Request

A batch server can be requested to write a string of characters to one or both output streams of an executing job. This request is primarily used by an operator to record a message for the user. The batch server will accept a *Message Job* request if all of the following conditions are true:

- The specified job is in the running state
- The user of the client is authorized to post a message to the designated job
- The specified job is owned by the server

When the server accepts the *Message Job* request, it will forward the request to the primary MoM for the job. Upon receiving the *Message Job* request from the server, the MoM will append the message string, followed by a newline character, to the file or files indicated. If no file is indicated, the message will be written to the standard error of the job.

### 3.5.6 Locate Job Request

A client may ask a server to return the location of a job that was created by or is owned by the server. When the server accepts the *Locate Job* request, it returns a *Locate Reply*. The request will be accepted if all of the following conditions are true:

- The server owns (manages) the job
- The server created the job
- The server is maintaining a record of the current location of the job

### 3.5.7 Delete Job Request

A *Delete Job* request asks a server to remove a job from the queue in which it exists and not place it elsewhere. The batch server will accept a *Delete Job* request if all of the following conditions are true:

- The user of the client is authorized to delete the designated job.
- The designated job is owned by the server.
- The designated job is in an eligible state. Eligible states are *queued*, *held*, *waiting*, *running*, and *transiting*.

If the job is in the running state, the server will forward the *Delete Job* request to the primary MoM responsible for the job. The MoM daemon will first send a SIGTERM signal to the job process group. After a delay specified by the delete request, or if not specified, the *kill\_delay* queue attribute, the MoM will send a SIGKILL signal to the job process group. The job is then placed into the *exiting* state. Option arguments exist to specify the delay in seconds between the SIGTERM and SIGKILL signals, as well as to force the deletion of the job even if the node it is running on is not responding.

### 3.5.8 Modify Job Request

A batch client makes a *Modify Job* request to the server to alter the attributes of a job. The batch server will accept a *Modify Job* request if all of the following conditions are true:

- The user of the client is authorized to make the requested modification to the job.
- The designated job is owned by the server.
- The requested modification is consistent with the state of the job.
- A requested resource change would not exceed the limits of the queue or server.
- An recognized resource is requested for a job in an execution queue.

When the batch server accepts a *Modify Job* request, it will modify all the specified attributes of the job. When the batch server rejects a *Modify Job* request, it will modify none of the attributes of the job.

### 3.5.9 Run Job Request

The *Run Job* request directs the server to place the specified job into immediate execution. The request is issued by a `qrun` command or by the PBS job scheduler.

### 3.5.10 Rerun Job Request

To rerun a job is to kill the members of the session (process) group of the job and leave the job in the execution queue. If the `Hold_Types` attribute is not *NONE*, the job is eligible to be re-scheduled for execution. The server will accept the *Rerun Job* request if all of the following conditions are true:

- The user of the client is authorized to rerun the designated job
- The `Rerunable` attribute of the job is set to *True*
- The job is in the running state
- The server owns the job

When the server accepts the *Rerun Job* request, the request will be forwarded to the primary MoM responsible for the job, who will then perform the following actions:

1. Send a `SIGKILL` signal to the session (process) group of the job
2. Send an `OBIT` notice to the server with resource usage information
3. The server will then requeue the job in the execution queue in which it was executing

If the `Hold_Types` attribute is not *NONE*, the job will be placed in the *held* state. If the `execution_time` attribute is a future time, the job will be placed in the *waiting* state. Otherwise, the job is placed in the *queued* state.

### 3.5.11 Hold Job Request

A client can request that one or more holds be applied to a job. The batch server will accept a *Hold Job* request if all of the following conditions are true:

- The user of the client is authorized to add any of the specified holds
- The batch server manages the specified job

When the server accepts the *Hold Job* request, it will add each specified hold which is not already present to the value of the `Hold_Types` attribute of the job. If the job is in the *queued* or *waiting* state, it is placed in the *held* state.

If the job is in *running* state:

If checkpoint / restart is supported by the host system, placing a hold on a running job will cause:

- a. The job is checkpointed
- b. The resources assigned to the job will be released
- c. The job is placed in the held state in the execution queue.

If checkpoint / restart is not supported, the server will only set the requested hold type(s). This will have no effect unless the job is rerun or restarted.

### 3.5.12 Release Job Request

A client can request that one or more holds be removed from a job. A batch server accepts a *Release Job* request if all of the following conditions are true:

- The user of the client is authorized to add (remove) any of the specified holds.
- The batch server manages the specified job.

When the server accepts the *Release Job* request, it will remove each specified type of hold from the value of the *Hold\_Types* attribute of the job. Normally, the job will then be placed in the queued state, unless another hold type is remaining on the job. However, if all holds have been removed, but the *Execution\_Time* attribute specifies a time in the future, the job is placed in the *waiting* state.

### 3.5.13 Move Job Request

A client can request a server to move a job to a new destination. The batch server will accept a *Move Job* request if all of the following conditions are true:

- The user of the client is authorized to remove the designated job from the queue in which the job resides
- The user of the client is authorized to submit a job to the new destination
- The designated job is owned by the server
- The designated job is in the *queued*, *held*, or *waiting* state
- The new destination is enabled
- The new destination is accessible. When the server accepts a *Move Job* request, it will
  - Queue the designated job at the new destination.
  - Remove the job from the current queue.

If the destination exists at a different server, the current server will transfer the job to the new server by sending a *Queue Job* request sequence to the target server. The server will ensure that a job is neither lost nor duplicated.

### 3.5.14 Select Jobs Request

A client is able to request from the server a list of jobs owned by that server that match a list of selection criteria. The request is a *Select Jobs* request. All the jobs owned by the server and which the user is authorized to query are initially eligible for selection. Job attribute and resource relationships listed in the request restrict the selection of jobs. Only jobs which have attributes and resources that meet the specified criteria will be selected. The server will reject the request if the queue portion of a specified destination does not exist on the server. When the request is accepted, the server will return a *Select Reply* containing a list of zero or more jobs that met the selection criteria.

### 3.5.15 Signal Job Request

A batch client is able to request that the server signal the session (process) group of a job. Such a request is called a *Signal Job* request. The batch server will accept a *Signal Job* request if all of the following conditions are true:

- The user of the client is authorized to signal the job
- The job is in the *running* state, except for the special signal “resume” when the job must be in the *Suspended* state
- The server owns the designated job
- The requested signal is supported by the host operating system. (The kill system call returns [ *EINVAL* ].)

When the server accepts a request to signal a job, it will forward the request to the primary MoM daemon responsible for the job, who will then send the signal requested by the client to the all processes in the job’s session.

### 3.5.16 Status Job Request

The status of a job or set of jobs at a destination may be requested with a *Status Job* request. The batch server will accept a *Status Job* request if all of the following conditions are true:

- The user of the client is authorized to query the status of the designated job
- The designated job is owned by the server

When the server accepts the request, it will return a *Job Status* message to the client. See the `qstat` command for details of which job attributes are returned to the client. If the request specifies a job identifier, status will be returned only for that job. If the request specifies a destination identifier, status will be returned for all jobs residing within the specified queue that the user is authorized to query.

## 3.6 Server to Server Requests

Server to server requests are a special category of client requests. They are only issued to a server by another server.

### 3.6.1 Track Job Request

A client that wishes to request an action be performed on a job must send a batch request to the server that currently manages the job.

As jobs are routed or moved through the batch network, finding the location of the job can be difficult without a tracking service. The Track Job request forms the basis for this service.

A server that queues a job sends a track job request to the server which created the job.

Additional backup location servers may be defined.

A server that receives a track job request records the information contained therein.

This information is made available in response to a Locate Job request.

### 3.6.2 Job Dependency

PBS supports job dependencies. A job, the “child”, can be declared to be dependent on one or more jobs, the “parents”. A parent may have any number of children. The dependency is specified as an attribute via the `qsub` command with the `-W depend=<dependency list>` option.

See [“qsub” on page 213 of the PBS Professional Reference Guide](#) for the complete specification of the dependency list, and [“Using Job Dependencies”, on page 107 of the PBS Professional User’s Guide](#) for how to use them.

When a server queues a job with a dependency type of *after*, *afterok*, *afternotok*, or *afterany* in an execution queue, the server will send a *Register Dependent Job* request to the server managing the job specified by the associated job identifier. The request will specify that the server is to register the dependency. This actually creates a corresponding *before* type dependency attribute entry on the parent (e.g. run job X *before* job Y). If the request is rejected because the parent job does not exist, the child job is aborted. If the request is accepted, a *system* hold is placed on the child job. When a parent job with any of the *before...* types of dependency reaches the required state, starts, or terminates, the server executing the parent job sends a *Register Dependent Job* request to the server managing the child job directing it to release the child job. If there are no other dependencies on other jobs, the system hold on the child job is removed. When a child job is submitted with an *on* dependency and the parent is submitted with any of the *before...* types of dependencies, the parent will register with the child. This causes the *on* dependency count to be reduced and a corre-

sponding *after...* dependency to be created for the child job. The result is a pairing between corresponding *before...* and *after...* dependency types. If the parent job terminates so that the child is not released, it is up to the user to correct the situation by either deleting the child job or by correcting the problem with the parent job and resubmitting it. If the parent job is resubmitted, it must have a dependency type of *before*, *beforeok*, *beforenotok*, or *beforeany* specified to connect it to the waiting child job.

## 3.7 Deferred Services

The PBS server uses an internal mechanism of deferred services to handle some work asynchronously.

Servers use deferred services for these job-related tasks:

- File staging
- Job selection
- Job initiation
- Job routing
- Job exit
- Job abort
- Rerunning jobs after a server restart

The following rules apply to deferred services used for jobs:

- If the server cannot complete a deferred service for a reason which is permanent, the job is aborted
- If the service cannot be completed at the current time but may be completed later, the service is retried a finite number of times

### 3.7.1 Job Scheduling

If a scheduler's `scheduling` attribute is *True*, the server requests scheduling cycles for that scheduler.

A scheduler runs in a loop. Inside each loop, it starts up, performs all of its work, and then stops. The scheduling cycle is triggered by a timer and by several possible events.

When there are no events to trigger the scheduling cycle, it is started by a timer. The time between starts is set in each scheduler's `scheduler_iteration` server attribute. The default value is 10 minutes.

The maximum duration of the cycle is set in each scheduler's `sched_cycle_length` attribute. A scheduler will terminate its cycle if the duration of the cycle exceeds the value of the attribute. The default value for the length of the scheduling cycle is 20 minutes. A scheduler does not include the time it takes to query dynamic resources in its cycle measurement.

### 3.7.1.1 Triggers for Scheduling Cycle

A scheduler starts when the following happen:

- The specified amount of time has passed since the previous start
- A job is submitted
- A job finishes execution.
- A new reservation is created
- A reservation starts
- Scheduling is enabled
- The server comes up
- A job is qrun
- A queue is started
- A job is moved to a local queue
- Eligible wait time for jobs is enabled
- A reservation is re-confirmed after being degraded
- A hook restarts the scheduling cycle

While a request for a scheduling cycle is outstanding, the connection to the scheduler is open, and the server will not make another request of the scheduler. If the scheduler `scheduling` attribute is *False*, the server will not contact the scheduler.

### 3.7.2 File Staging

PBS provides staging in before execution and staging out after execution. These services are requested via the `-W` option, which sets the stagein and stageout job attributes. The attributes specify the files to be staged:

`-W stagein=<execution path>@<input file storage host>:<input file storage path>[,...]`

`-W stageout=<execution path>@<output file storage host>:<output file storage path>[,...]`

The name *execution path* is the name of the file in the job's staging and execution directory (on the execution host). The *execution path* can be relative to the job's staging and execution directory, or it can be an absolute path.

The '@' character separates the execution specification from the storage specification.

The name *storage path* is the file name on the host specified by *storage host*. For stagein, this is the location where the input files come from. For stageout, this is where the output files end up when the job is done. The user must specify a hostname. The name can be absolute, or it can be relative to your home directory on the machine named *storage host*.

For stagein, the direction of travel is **from** *storage path* **to** *execution path*.

For stageout, the direction of travel is **from** *execution path* **to** *storage path*.

A request to stage in a file tells the server to direct MoM to copy a file from the storage location to the execution location. The user must have authority to access the file under the same username under which the job will be run. The storage file is not modified or destroyed. The file will be available before the job is initiated. If a file cannot be staged in for any reason, any files which were staged in are deleted and the job is placed in the wait state and mail is sent to the job owner.

A request to stage out a file tells the server to direct MoM to move a file from the execution location to the storage location. This service is performed after the job has completed execution and regardless of job exit status. If a file cannot be moved, mail is sent to the job owner. If a file is successfully staged out, the local file is deleted.

For file copy mechanism information, see ["Setting File Transfer Mechanism" on page 549 in the PBS Professional Administrator's Guide](#).

### 3.7.3 Job Start

The server receives *Run Job* requests from a PBS scheduler and the `qrun` command. If a request is authenticated, the server forwards the *Run Job* request to the primary MoM for the job; the primary MoM is chosen by the scheduler or specified in the *Run Job* request.

See the sequence of events in ["Sequence of Events for Start of Job" on page 516 in the PBS Professional Administrator's Guide](#).

The primary MoM creates a session leader that runs the shell program specified in the job's `Shell_Path_List` attribute.

The pathname of the script and any script arguments are passed as parameters to the shell. If the pathname of the shell is relative, the MoM searches its execution path, `$PATH`, for the shell. If the pathname of the shell is omitted or is the null string, the MoM uses the login shell for the job owner.

The MoM determines the job owner using the following rules:

1. Choose the username in the `User_List` job attribute whose hostname matches the execution host.
2. Choose the username in the `User_List` job attribute which has no associated hostname.
3. Use the username from the `Job_Owner` job attribute.

The MoM creates and sets the following environment variables in the environment of the session leader of the job:

- `PBS_ENVIRONMENT`; value set to the string `"PBS_BATCH"`
- `PBS_QUEUE`; value set to the name of the execution queue

PBS provides each job with environment variables where the job runs. PBS takes some from the submission environment, and creates others. Job submitters can create environment variables for their jobs. The environment variables created by PBS begin with `"PBS_"`. The environment variables that PBS takes from the job submission environment begin with `"PBS_O_"`.

For example, here are a few of the environment variables that accompany a job submitted by user1, with typical values:

```
PBS_O_HOME=/u/user1
PBS_O_LOGNAME=user1
PBS_O_PATH=/usr/bin:/usr/local/bin:/bin
PBS_O_SHELL=/bin/tcsh
PBS_O_HOST=host1
PBS_O_WORKDIR=/u/user1
PBS_JOBID=16386.server1
```

For a complete list of PBS environment variables, ["PBS Environment Variables" on page 399 of the PBS Professional Reference Guide](#).

The MoM puts all of the variables found in the job's `Variable_List` attribute, with their corresponding values, into the environment of the job's session leader.

The MoM places the specified limits on host-level resources.

If the job has been run before and is now being rerun, the MoM will ensure that the standard output and standard error streams of the job are appended to the prior streams, if any.

If the MoM and host system support accounting, the MoM will use the value of the `Account_Name` job attribute as required by the host system.

If the MoM and host system support checkpoint, the MoM will set up checkpointing of the job according to the value of the `Checkpoint` job attribute. If checkpoint is supported and the `Checkpoint` attribute requests checkpointing at the minimum interval or at an interval less than the minimum interval for the queue, then checkpoint will be set for an interval given by the queue attribute `checkpoint_min`.

The MoM will set up the standard output stream and the standard error stream of the job according to the table labeled ["How k, sandbox, o, and e Options to qsub Affect stdout and stderr", on page 41 of the PBS Professional User's Guide](#).

### 3.7.4 Job Routing

The PBS server performs all job routing tasks. Job routing is described in ["Routing Queues" on page 25 in the PBS Professional Administrator's Guide](#).

If the routing destination is at another server, the current server uses a *Queue Job* request to move the job to the new destination.

### 3.7.5 Job Exit

When the session leader of a batch job exits, the MoM will perform the following actions in the order listed:

- Place the job in the exiting state.
- Manage the output and error streams of the job, according to ["How k, sandbox, o, and e Options to qsub Affect stdout and stderr", on page 41 of the PBS Professional User's Guide](#).
- If the `Mail_Points` job attribute contains the value `e (EXIT)`, the server will send mail to the users listed in the `Mail_Users` job attribute.
- Files are staged out
- Frees the resources allocated to the job. The actual releasing of resources assigned to the processes of the job is performed by the kernel. PBS will free the resources which it reserved for the job by decrementing the `resources_used` generic data item for the queue and server.
- The job will be removed from the execution queue.

### 3.7.6 Aborting Job

If the server aborts a job and the `Mail_Points` job attribute contains the value `a (ABORT)`, the server will send mail to the users listed in the `Mail_Users` job attribute. The mail message will contain the reason the job was aborted.

### 3.7.7 Timed Events

The server performs certain events at a specified time or after a specified time delay. Examples:

- A job may have its `Execution_Time` attribute set to a time in the future. When that time is reached, the job state is updated.
- If the server is unable to make connection with another server, it is to retry after a time specified by the routing queue attribute `route_retry_time`.

### 3.7.8 Event Logging

The PBS server maintains an event logfile, the format and contents of which are documented in ["Event Logging" on page 536 in the PBS Professional Administrator's Guide](#).

### 3.7.9 Accounting

The PBS server maintains an accounting file, the format and contents of which are documented in ["Accounting" on page 607 in the PBS Professional Administrator's Guide](#).

## 3.8 Resource Management

PBS performs resource allocation at job initiation in two ways depending on the support provided by the host system. Resources are either reservable or non reservable.

### 3.8.1 Resource Limits

A job submitter can specify limits for resources used by their job, by requesting those amounts. If the job exceeds those limits, it is aborted. The administrator can specify default limits for resource use by jobs. Defaults are specified at the server and at queues. Defaults are applied when limits are not specified by the submitter. The administrator can also use hooks to set resource requests, and thereby limits, in whatever way is useful. See ["Allocating Default Resources to Jobs" on page 247 in the PBS Professional Administrator's Guide](#) and the *PBS Professional Plugins (Hooks) Guide*.

If the submitter does not specify a limit for a resource and there is no default, the job can use an unlimited amount of the resource.

### 3.8.2 Resource Names

For additional information, see ["List of Built-in Resources" on page 259 of the PBS Professional Reference Guide](#) where all resource names are documented.

## 3.9 Network Protocol

The PBS system fits into a client - server model, with a batch client making a request of a batch server and the server replying. This client - server communication necessitates an interprocess communication method and a data exchange (data encoding) format. Since the client and server may reside on different systems, the interprocess communication must be supportable over a network.

While the basic PBS system fits nicely into the client - server model, it also has aspects of a transaction system. When jobs are being moved between servers, it is critical that the jobs are not lost or replicated. Updates to a batch job must be applied once and only once. Thus the operation must be atomic. Most of the client to server requests consist of a single message. Treating these requests as an atomic operation is simple. One request, "Queue Job", is more complex and involves several messages, or subrequests, between the client and the server. Any of these subrequests might be rejected by the server. It is important that either side of the connection be able to abort the request (transaction) without losing or replicating the job. The network connection also might be lost during the request. Recovery from a partially transmitted request sequence is critical. The sequence of recovery from lost connections is discussed in the Queue Job Request description.

The batch system data exchange protocol must be built on top of a reliable stream connection protocol. PBS uses TCP/IP and the socket interface to the network. Either the Simple Network Interface, SNI, or the Detailed Network Interface, DNI, as specified by POSIX.12, Protocol Independent Interfaces, could be used as a replacement.

---

### 3.9.1 General DIS Data Encoding

The purpose of the “Data is Strings” encoding is to provide a simple, fast, small, machine-independent form for encoding data to a character string and back again. Because data can be decoded directly into the final internal data structures, the number of data copy operations are reduced. Data items are represented as people think of them, but preceded with a count of the length of each data item.

For small positive integers, it is impossible to tell from the encoded data whether they came from signed or unsigned chars, shorts, ints, or longs. Similarly, for small negative numbers, the only thing that can be determined from the encoded data is that the source datum was not unsigned. It is impossible to tell the word size of the encoding machine, or whether it uses 2’s complement, one’s complement or sign - magnitude representation, or even if it uses binary arithmetic. All of the basic C data types are handled. Signed and unsigned chars, shorts, ints, longs produce integers. NULL-terminated and counted strings produce counted strings (with the terminating NULL removed). Floats, doubles, and long doubles produce real numbers. Complex data must be built up from the basic types. Note that there is no type tagging, so the type and sequence of data to be decoded must be known in advance.

# Developer Headers and Libraries

## 4.1 Location of API Libraries

All of the libraries containing the PBS API are installed by default in `$PBS_EXEC/lib/`.

## 4.2 Location of Header Files

Header files used by your code are found in `$PBS_EXEC/include`.

## 4.3 Developer Package

We provide a development package as an RPM package. The files in this package are useful only for developing and compiling software that interfaces with PBS. They are not required to run PBS.

The development package is named `pbspro-devel` and contains the following headers and libraries:

```
/opt/pbs/include/pbs_error.h
/opt/pbs/include/pbs_if1.h
/opt/pbs/include/rm.h
/opt/pbs/include/tm.h
/opt/pbs/include/tm_.h
/opt/pbs/lib/libattr.a
/opt/pbs/lib/liblog.a
/opt/pbs/lib/libnet.a
/opt/pbs/lib/libpbs.a
/opt/pbs/lib/libpbs_sched.a
/opt/pbs/lib/libsite.a
```

These files were previously in the `pbspro-server`, `pbspro-client` and `pbspro-execution` packages.

The `pbspro-devel` package also contains the `README` file, like the other PBS Professional RPM packages:

```
/usr/share/doc/pbspro-devel-19.0.0/README.md
```

You can install the `pbspro-devel` package separately from the other PBS packages. This package does not conflict with other PBS packages.

## 4.4 Batch Interface Library

The primary external application programming interface to PBS is the Batch Interface Library, or IFL. This library provides all of the batch service requests used for PBS. The IFL provides a user-callable function corresponding to each batch client command in PBS Professional. Each command generates its own batch service request. You request service from a batch server by calling the appropriate library routine and passing it the required arguments.

The user-callable routines are declared in the header file `PBS_ifl.h`.

We describe the Batch Interface Library in [section , “Batch Interface Library \(IFL\)”, on page 21](#).

### 4.4.1 Error Codes

Error codes are available in the header file `PBS_error.h`.

### 4.4.2 Windows Requirement

To use `pbs_connect ( )` with Windows, initialize the network library and link with `winsock2`. Call `winsock_init()` before calling `pbs_connect ( )`, and link against the `ws2_32.lib` library.

## 4.5 Example Compilation Line

A compile command might look like the following:

```
cc mycode.c -I/usr/pbs/include -L/usr/pbs/lib -lpbs
```

# Batch Interface Library (IFL)

You can use the commands in this library to build your new batch clients. For example, you can customize your job status display instead of using `qstat`, build new control commands, or use these commands to build jobs that can get their own status or spawn new jobs.

## 5.1 Interface Library Overview

The primary external application programming interface to PBS is the Batch Interface Library, or IFL. This library provides all of the batch service requests used for PBS. The IFL provides a user-callable function corresponding to each batch client command in PBS Professional. Each command generates its own batch service request. You request service from a batch server by calling the appropriate library routine and passing it the required arguments.

The user-callable routines are declared in the header file `PBS_ifl.h`.

Error codes are available in the header file `PBS_error.h`.

### 5.1.1 Connection to Server

We provide network connection management routines to be used with our API commands.

You open a connection with a batch server via a call to `pbs_connect()`, which returns a connection handle to the desired server. You can open multiple connections, and you can use each connection for multiple service requests.

When you are finished using a connection to the server, close it via a call to `pbs_disconnect()`.

### 5.1.2 Authentication

Before it establishes a connection, `pbs_connect()` `fork()`s and `exec()`s a `pbs_iff` process. The `pbs_iff` process provides a credential which validates the user's identity, and prevents a user from spoofing another user's identity. This credential is included in each batch request sent to the server, and consists of the following:

- The user's name from the password file based on running `pbs_iff`'s "real uid" value
- The unprivileged, client-side port value associated with the original `pbs_connect()` request message to the server.

The server checks the entries in its connection table for a matching entry which is not yet marked authenticated. The server requires that the matching entry came from a privileged, remote-end, port value.

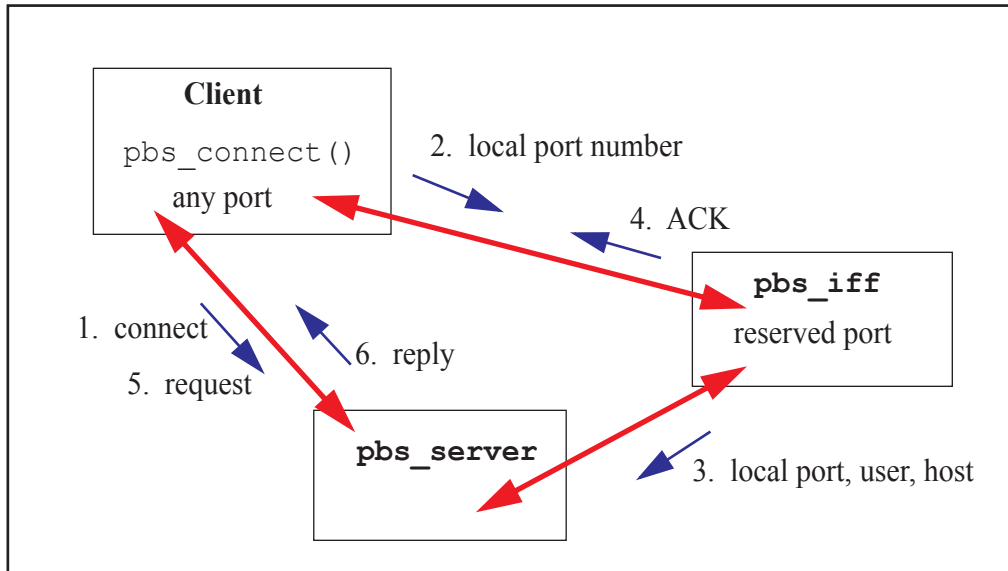

Figure 4-1: Interface Between Client, IFF, and Server

### 5.1.3 Windows Requirement

To use `pbs_connect()` with Windows, initialize the network library and link with `winsock2`. Call `winsock_init()` before calling `pbs_connect()`, and link against the `ws2_32.lib` library.

## 5.3 pbs\_alterjob

alter a PBS batch job

### 5.3.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_alterjob(int connect, char *jobID, struct attropi *change_list, char *extend)
```

### 5.3.2 Description

Issues a batch request to alter a batch job.

This command generates a *Modify Job* (11) batch request and sends it to the server over the connection specified by connect.

Job state may affect which attributes can be altered. See [“qalter” on page 127 of the PBS Professional Reference Guide](#).

### 5.3.3 Arguments

connect

Return value of pbs\_connect ( ). Specifies connection over which to send batch request to server.

jobID

ID of job or job array to be altered. Format for a job:

<sequence number>.<server name>

Format for an array job:

<sequence number>[<server name>]

change\_list

Pointer to a list of attributes to change. Each attribute is described in an attropi structure, defined in pbs\_ifl.h as:

```
struct attropi {
 struct attropi *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

extend

Character string for extensions to command. Not currently used.

#### 5.3.3.1 Members of attropi Structure

next

Points to next attribute in list. A null pointer terminates the list.

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a pointer to a null string.

If the resource is already present in the job's **Resource\_List** attribute, the value is altered as specified. Otherwise the resource is added.

**value**

Points to a string containing the value of the attribute or resource.

**op**

Defines the operation to perform on the attribute or resource. For this command, operators are *SET*, *UNSET*, *INCR*, *DECR*.

### 5.3.4 Return Value

The routine returns *0* (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.3.5 See Also

[qalter](#), [qhold](#), [qrls](#), [qsub](#), [pbs\\_connect](#), [pbs\\_holdjob](#), [pbs\\_rlsjob](#)

## 5.4 pbs\_asyrundjob

run an asynchronous PBS batch job

### 5.4.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_asyrundjob(int connect, char *jobID, char *location, char *extend)
```

### 5.4.2 Description

Issues a batch request to run a batch job.

Generates an *Asynchronous Run Job* (23) request and sends it to the server over the connection specified by connect.

The server validates the request and replies before initiating the execution of the job.

You can use this version of the call to reduce latency in scheduling, especially when the scheduler must start a large number of jobs.

### 5.4.3 Required Privilege

You must have Manager or Operator privilege to use this command.

### 5.4.4 Arguments

connect

Return value of `pbs_connect ( )`. Specifies connection handle over which to send batch request to server.

jobID

ID of job to be run.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

location

Location where job should run, and optionally resources to use. Same as `qrun -H:`

`-H <vnode specification without resources>`

The *vnode specification without resources* has this format:

`(<vchunk>)[+(<vchunk>) ...]`

where *vchunk* has the format

`<vnode name>[+<vnode name> ...]`

Example:

`-H (VnodeA+VnodeB)+(VnodeC)`

PBS applies one requested chunk from the job's selection directive in round-robin fashion to each *vchunk* in the list. Each *vchunk* must be sufficient to run the job's corresponding chunk, otherwise the job may not execute correctly.

#### -H <vnode specification with resources>

The *vnode specification with resources* has this format:

(<vchunk>)[+(<vchunk>) ...]

where *vchunk* has the format

<vnode name>:<vnode resources>[+<vnode name>:<vnode resources> ...]

and where *vnode resources* has the format

<resource name>=<value>[:<resource name>=<value> ...]

Example:

```
-H (VnodeA:mem=100kb:ncpus=1) +(VnodeB:mem=100kb:ncpus=2+VnodeC:mem=100kb)
```

PBS creates a new selection directive from the *vnode specification with resources*, using it instead of the original specification from the user. Any single resource specification results in the job's original selection directive being ignored. Each *vchunk* must be sufficient to run the job's corresponding chunk, otherwise the job may not execute correctly.

If the job being run requests `-l place=exclhost`, take extra care to satisfy the `exclhost` request. Make sure that if any vnodes are from a multi-vnoded host, all vnodes from that host are allocated. Otherwise those vnodes can be allocated to other jobs.

#### extend

Character string for extensions to command. Not currently used.

## 5.4.5 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

## 5.4.6 See Also

[qrun](#), [pbs\\_connect](#), [pbs\\_runjob](#)

## 5.5 pbs\_confirmresv

confirm a PBS reservation

### 5.5.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_confirmresv(int connect, char *reservationID, char *location, unsigned long start_time, char *extend)
```

### 5.5.2 Description

Issues a batch request to confirm a PBS advance, standing, or maintenance reservation.

This function generates a *Confirm Reservation* (75) batch request and sends it to the server over the connection specified by `connect`.

### 5.5.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection over which to send batch request to server.

`reservationID`

Reservation to be confirmed.

Format for advance reservation:

*R*<sequence number>.<server name>

Format for standing reservation:

*S*<sequence number>.<server name>

Format for maintenance reservation:

*M*<sequence number>.<server name>

`location`

String describing vnodes and resources to be used for reservation. Format:

(<vchunk>)[+(<vchunk>) ...]

where *vchunk* has the format

<vnode name>:<vnode resources>[+<vnode name>:<vnode resources> ...]

and where *vnode resources* has the format

<resource name>=<value>[:<resource name>=<value> ...]

Example:

```
-H (VnodeA:mem=100kb:ncpus=1) +(VnodeB:mem=100kb:ncpus=2+VnodeC:mem=100kb)
```

`start_time`

Unsigned long containing start time in seconds since epoch. Used only for ASAP reservations (reservations created by using `pbs_rsub -W qmove=<jobID>` on an existing job).

extend

Character string for specifying confirmation/non-confirmation action:

- To confirm a normal reservation, pass in *PBS\_RESV\_CONFIRM\_SUCCESS*.
- To have an unconfirmed reservation deleted, pass in *PBS\_RESV\_CONFIRM\_FAIL*.
- To have the scheduler set the time when it will try to reconfirm a degraded reservation, pass in *PBS\_RESV\_CONFIRM\_FAIL*.

## 5.5.4 Return Value

The routine returns *0* (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

## 5.5.5 See Also

---

## 5.6 pbs\_connect

return a connection handle from a PBS batch server

### 5.6.1 Synopsis

```
#include <pbs_error.h>
#include <pbs_ifl.h>
int pbs_connect(char *server)
```

### 5.6.2 Description

This function establishes a virtual stream (TCP/IP) connection with the specified batch server.

Returns a connection handle.

`pbs_connect ( )` determines whether or not the complex has a failover server configured. It also determines which server is the primary and which is the secondary.

### 5.6.3 Arguments

**server**

Specifies name of server to connect to. Format:

`<hostname>[:<port>]`

If you do not specify a port, PBS uses the default.

If *server* is a null pointer or a null string, this function opens a connection to the default server. The default server is specified in the `PBS_DEFAULT` environment variable or the `PBS_SERVER` parameter in `/etc/pbs.conf`.

### 5.6.4 Usage

Use this function to establish a connection handle to the desired server before calling any of the other `pbs_*` API functions. They will send their batch requests over the connection established by this function. You can send multiple requests over one connection.

### 5.6.5 Cleanup

After you are done using the connection handle, close the connection via a call to `pbs_disconnect ( )`.

### 5.6.6 Side Effects

The global variable `pbs_server` is declared in `pbs_ifl.h`. This variable is set on return to point to the server name to which `pbs_connect ( )` connected or attempted to connect.

---

## 5.6.7 Windows Requirement

In order to use `pbs_connect()` with Windows, initialize the network library and link with `winsock2`. To do this, call `winsock_init()` before calling `pbs_connect()`, and link against the `ws2_32.lib` library.

## 5.6.8 Return Value

On success, the routine returns a connection handle which is a non-negative integer.

If an error occurred, the routine returns -1, and the error number is available in the global integer `pbs_errno`.

## 5.6.9 See Also

[`pbs\_terminate`](#), [`pbs\_server`](#)

## 5.7 pbs\_default

return the name of the default PBS server

### 5.7.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_default()
```

### 5.7.2 Description

Returns a pointer to a character string containing the name of the default PBS server.

The default server is specified in the PBS\_DEFAULT environment variable or the PBS\_SERVER parameter in `/etc/pbs.conf`.

### 5.7.3 Return Value

On success, returns a pointer to a character string containing the name of the default PBS server. You do not need to free the character string.

Returns null if it cannot determine the name of the default server.

## 5.8 pbs\_deljob

delete a PBS batch job

### 5.8.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_deljob(int connect, char *jobID, char *extend)
```

### 5.8.2 Description

Issues a batch request to delete a batch job.

This function generates a *Delete Job* (6) batch request and sends it to the server over the connection specified by `connect`.

If the batch job is running, the MoM sends the SIGTERM signal followed by SIGKILL.

If the batch job is deleted by a user other than the job owner, PBS sends mail to the job owner.

### 5.8.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`jobID`

ID of job, job array, subjob, or range of subjobs to be deleted.

Format for a job:

`<sequence number>.<server name>`

Format for an array job:

`<sequence number>[<server name>]`

Format for a subjob:

`<sequence number>[<index>][<server name>]`

Format for a range of subjobs:

`<sequence number>[<first>-<last>][<server name>]`

`extend`

Character string for extensions to command. If the string is not null, it is appended to the message mailed to the job owner.

### 5.8.4 Return Value

The routine returns 0 (*zero*) on success.

On error, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.8.5 See Also

[qdel](#), [pbs\\_connect](#)

---

## 5.9 pbs\_delresv

delete a reservation

### 5.9.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_delresv(int connect, char *reservationID, char *extend)
```

### 5.9.2 Description

Issues a batch request to delete a reservation.

This function generates a *Delete Reservation* (72) batch request and sends it to the server over the connection specified by `connect`.

If the reservation is in state *RESV\_RUNNING*, and there are jobs in the reservation queue, those jobs are deleted before the reservation is deleted.

### 5.9.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection over which to send batch request to server.

`reservationID`

Reservation to be deleted.

Format for advance reservation:

*R*<sequence number>.<server name>

Format for standing reservation:

*S*<sequence number>.<server name>

Format for maintenance reservation:

*M*<sequence number>.<server name>

`extend`

Character string for extensions to command. Not currently used.

### 5.9.4 Return Value

The routine returns 0 (zero) on success.

On error, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.9.5 See Also

[pbs\\_rdel](#), [pbs\\_connect](#)

## 5.10 pbs\_disconnect

disconnect from a PBS batch server

### 5.10.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_disconnect(int connect)
```

### 5.10.2 Description

Closes the virtual stream connection to a PBS batch server. Connection was previously returned from a call to `pbs_connect()`.

### 5.10.3 Arguments

`connect`

Connection handle to be closed. Return value of `pbs_connect()`. Specifies connection used earlier to send batch requests to server.

### 5.10.4 Return Value

The routine returns *0* (*zero*) after successfully closing the connection.

If an error occurred, the routine returns -1, and the error number is available in the global integer `pbs_errno`.

### 5.10.5 See Also

---

## 5.11 pbs\_geterrmsg

get error message for most recent PBS batch operation

### 5.11.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_geterrmsg(int connect)
```

### 5.11.2 Description

Returns most recent error message text associated with a batch server request.

If a preceding batch interface library call over the connection specified by `connect` returned an error from the server, the server may have created an associated text message. If there is a text message, this function returns a pointer to the text message.

### 5.11.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection handle over which to request error message from server.

### 5.11.4 Return Value

If the server returned an error and created an error text string in reply to a previous batch request, this function returns a pointer to the text string. The text string is null-terminated.

If the server does not have an error text string, this function returns a null pointer.

The text string is a global variable; you do not need to free it.

### 5.11.5 See Also

[pbs\\_connect](#)

## 5.12 pbs\_holdjob

place a hold on a PBS batch job

### 5.12.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_holdjob(int connect, char *jobID, char *hold_type, char *extend)
```

### 5.12.2 Description

Issues a batch request to place a hold on a job or job array.

This function generates a *Hold Job* (7) batch request sends it to the server over the connection specified by `connect`.

### 5.12.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection over which to send batch request to server.

`jobID`

ID of job which is to be held.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

`hold_type`

Type of hold to apply to job or job array. Valid values are defined in `pbs_ifl.h`. If `hold_type` is a null pointer or points to a null string, PBS applies a *User* hold to the job or job array.

`extend`

Character string for extensions to command. Not currently used.

### 5.12.4 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.12.5 See Also

[qhold](#), [pbs\\_connect](#), [pbs\\_alterjob](#), [pbs\\_rlsjob](#)

## 5.13 pbs\_locjob

return current location of a PBS batch job

### 5.13.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_locjob(int connect, char *jobID, char *extend)
```

### 5.13.2 Description

Issues a batch request to locate a batch job or job array.

This function generates a *Locate Job* (8) batch request and sends it to the server over the connection specified by `connect`.

If the server currently manages the batch job, or knows which server does currently manage the job, the server returns the location of the job.

### 5.13.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`jobID`

ID of job to be located.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

`extend`

Character string for extensions to command. Not currently used.

### 5.13.4 Cleanup

The character string returned by `pbs_locjob()` is allocated by `pbs_locjob()`. You must free it via a call to `free()`.

### 5.13.5 Return Value

On success, returns a pointer to a character string containing current location. Format:

`<server name>`

On failure, returns a null pointer, and the error number is available in the global integer `pbs_erno`.

### 5.13.6 See Also

[pbs\\_connect](#)

---

## 5.14 pbs\_manager

modify a PBS batch object

### 5.14.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_manager(int connect, int command, int object_type, char *object_name, struct attropl *attrib_list, char *extend)
```

### 5.14.2 Description

Issues a batch request to perform administrative functions at a server.

Generates a *Manager* (9) batch request and sends it to the server over the connection specified by `connect`.

You can use this to create, delete, and set attributes of objects such as queues.

### 5.14.3 Required Privilege

This function requires Manager or Operator privilege depending on the operation, and root privilege when used with hooks.

When not used with hooks:

- Functions MGR\_CMD\_CREATE and MGR\_CMD\_DELETE require PBS Manager privilege.
- Functions MGR\_CMD\_SET and MGR\_CMD\_UNSET require PBS Manager or Operator privilege.

When used with hooks:

- All commands require root privilege on the server host.
- Functions MGR\_CMD\_IMPORT, MGR\_CMD\_EXPORT, and MGR\_OBJ\_HOOK are used only with hooks, and therefore require root privilege on the server host.
- Hook commands are run at the server host.

### 5.14.4 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`command`

Operation to be performed. Valid values are specified in `pbs_ifl.h`.

`object_type`

Specifies type of object on which command is to operate. Valid values are specified in `pbs_ifl.h`.

`object_name`

Name of object on which to operate.

**attrib\_list**

Pointer to a list of attributes to be operated on. Each attribute is described in an **attropl** structure, defined in **pbs\_ifl.h** as:

```
struct attropl {
 struct attropl *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

**extend**

Character string for extensions to command. Not currently used.

### 5.14.4.1 Members of attropl Structure

**next**

Points to next attribute in list. A null pointer terminates the list.

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

If the resource is already present in the object's attribute, the value is altered as specified. Otherwise the resource is added.

**value**

Points to a string containing the new value of the attribute or resource. For parameterized limit attributes, this string contains all parameters for the attribute.

**op**

Defines the manner in which the new value is assigned to the attribute or resource. The operators used for this function are *SET*, *UNSET*, *INCR*, *DECR*.

### 5.14.5 Usage for Hooks

When importing a hook or hook configuration file:

- Set *command* to *MGR\_CMD\_IMPORT*
- Set *object\_type* to *SITE\_HOOK* (or *PBS\_HOOK* if you are importing a configuration file for a built-in hook; you cannot import a built-in hook)
- Set *object\_name* to the name of the hook
- In one *attropl* structure:
  - Set *name* to “*content-type*”
  - Set *value* to “*application/x-python*” for a hook, or “*application/x-config*” for a configuration file
- In another *attropl* structure:
  - Set *name* to “*content-encoding*”
  - Set *value* to “*default*” or “*base64*”
- In a third *attropl* structure:
  - Set *name* to “*input-file*”
  - Set *value* to the name of the input file
- Set *op* to *SET*

When exporting a hook or hook configuration file:

- Set *command* to *MGR\_CMD\_EXPORT*
- Set *object\_type* to *SITE\_HOOK* (or *PBS\_HOOK* if you are exporting a configuration file for a built-in hook; you cannot export a built-in hook)
- Set *object\_name* to the name of the hook
- In one *attropl* structure:
  - Set *name* to “*content-type*”
  - Set *value* to “*application/x-python*” for a hook, or “*application/x-config*” for a configuration file
- In another *attropl* structure:
  - Set *name* to “*content-encoding*”
  - Set *value* to “*default*” or “*base64*”
- In a third *attropl* structure:
  - Set *name* to “*output-file*”
  - Set *value* to the name of the output file
- Set *op* to *SET*

See the *PBS Professional Hooks Guide*.

### 5.14.6 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer *pbs\_errno*.

### 5.14.7 See Also

[qmgr](#), [pbs\\_connect](#)

## 5.15 pbs\_modify\_resv

modify a PBS reservation

### 5.15.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_modify_resv(int connect, char *reservationID, struct attrop1 *attrib_list, char *extend)
```

### 5.15.2 Description

Issues a batch request to modify a reservation.

Generates a *Modify Reservation* (91) batch request and sends it to the server over the connection specified by `connect`.

### 5.15.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection over which to send batch request to server.

`reservationID`

Reservation to be modified.

Format for advance reservation:

*R<sequence number>.<server name>*

Format for standing reservation:

*S<sequence number>.<server name>*

`attrib_list`

Pointer to a list of attributes to modify. Each attribute is described in an `attrop1` structure, defined in `pbs_ifl.h` as:

```
struct attrop1 {
 struct attrop1 *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

For any attribute that is not specified or that is a null pointer, PBS takes the default action for that attribute. The default action is to assign the default value or to not pass the attribute with the reservation; the action depends on the attribute.

`extend`

Character string for extensions to command. Not currently used.

### 5.15.3.1 Members of attropi Structure

**next**

Points to next attribute in list. A null pointer terminates the list.

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

If the resource is already present in the reservation's **Resource\_List** attribute, the value is altered as specified. Otherwise the resource is added.

**value**

Points to a string containing the value of the attribute or resource.

**op**

Operator. The only allowed operator for this function is *SET*.

### 5.15.4 Return Value

On success, returns a character string containing the reservation ID assigned by the server.

On failure, returns a null pointer, and the error number is available in the global integer **pbs\_erno**.

### 5.15.5 Cleanup

The space for the reservation ID string is allocated by **pbs\_modify\_resv()**.

Release the reservation ID via a call to **free()** when no longer needed.

### 5.15.6 See Also

## 5.16 pbs\_movejob

move a PBS batch job to a new destination

### 5.16.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_movejob(int connect, char *jobID, char *destination, char *extend)
```

### 5.16.2 Description

Issues a batch request to move a job or job array to a new destination.

Generates a *Move Job* (12) batch request and sends it to the server over the connection specified by `connect`.

Moves specified job or job array from its current queue and server to the specified queue and server.

You cannot move a job in the Running, Transiting, or Exiting states.

### 5.16.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`jobID`

ID of job to be moved.

Format for a job:

*<sequence number>.<server name>*

Format for a job array:

*<sequence number>[<server name>]*

`destination`

New location for job or job array. Formats:

*<queue name>@<server name>*

Specified queue at specified server

*<queue name>*

Specified queue at default server

*@<server name>*

Default queue at specified server

*@default*

Default queue at default server

*(null pointer or null string)*

Default queue at default server

`extend`

Character string for extensions to command. Not currently used.

## 5.16.4 Return Value

The routine returns *0* (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

## 5.16.5 See Also

[qmove](#), [pbs\\_connect](#)

## 5.17 pbs\_msgjob

record a message for a running PBS batch job

### 5.17.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_msgjob(int connect, char *jobID, int file, char *message, char *extend)
```

### 5.17.2 Description

Issues a batch request to write a message in one or more output files of a batch job.

Generates a *Message Job* (10) batch request and sends it to the server over the connection specified by `connect`.

You can write a message into a job's `stdout` and/or `stderr` files. Can be used on jobs or subjobs, but not job arrays or ranges of subjobs.

### 5.17.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`jobID`

ID of job into whose output file(s) to write.

Format for a job:

`<sequence number>.<server name>`

Format for a subjob:

`<sequence number>[<index>].<server name>`

`file`

Indicates whether to write to `stdout`, `stderr`, or both:

1

Writes to `stdout`

2

Writes to `stderr`

3

Writes to `stdout` and `stderr`

`message`

Character string to be written to output file(s).

`extend`

Character string for extensions to command. Not currently used.

### 5.17.4 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.17.5 See Also

[qmsg](#), [pbs\\_connect](#)

## 5.18 pbs\_orderjob

swap positions of two PBS batch jobs

### 5.18.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_orderjob(int connect, char *jobID1, char *jobID2, char *extend)
```

### 5.18.2 Description

Issues a batch request to swap the positions of two jobs.

Generates an *Order Job* (50) batch request and sends it to the server over the connection specified by `connect`.

Can be used on jobs and job arrays. Can be used on jobs in different queues. Both jobs must be at the same server.

You cannot swap positions of jobs that are running.

### 5.18.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`jobID1, jobID2`

IDs of jobs to be swapped.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

`extend`

Character string for extensions to command. Not currently used.

### 5.18.4 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.18.5 See Also

[qmove](#), [qorder](#), [qsub](#), [pbs\\_connect](#)

## 5.19 pbs\_preempt\_jobs

preempt a list of jobs

### 5.19.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
preempt_job_info *pbs_preempt_jobs(int connect, char **jobID_list)
```

### 5.19.2 Description

Sends the server a list of jobs to be preempted.

Sends a *Preempt Jobs* (93) batch request to the server over the connection specified by `connect`.

Returns a list of preempted jobs along with the method used to preempt each one.

### 5.19.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection handle over which to send batch request to server.

`jobID_list`

List of job IDs to be preempted, as a null-terminated array of pointers to strings.

Format for a job ID:

`<sequence number>.<server name>`

Format for a job array ID:

`<sequence number>[<server name>]`

For example:

```
const char *joblist[3];
joblist[0]="123@myserver";
joblist[1]="456@myserver";
joblist[2]=NULL;
```

### 5.19.4 Return Value

Returns a list of preempted jobs. Each job is represented in a `preempt_job_info` structure, which has the following fields:

`job_id`

The job ID, in a `char*`

`preempt_method`

How the job was preempted, in a `char`:

S

The job was preempted using suspension.

C

The job was preempted using checkpointing.

- R     The job was preempted by being requeued.
- D     The job was preempted by being deleted.
- 0 (zero)     The job could not be preempted.

### 5.19.5 Cleanup

You must free the list of preempted jobs by passing it directly to `free( )`.

---

## 5.20 pbs\_relnodesjob

release some or all of the non-primary-execution-host vnodes assigned to a PBS job

### 5.20.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_relnodesjob (int connect, char *jobID, char *vnode_list, char *extend)
```

### 5.20.2 Description

Issues a batch request to release some or all of the vnodes of a batch job.

Generates a *RelnodesJob* (90) batch request and sends it to the server over the connection specified by `connect`.

You cannot release vnodes on the primary execution host.

You can use this on jobs and subjobs, but not on job arrays or ranges of subjobs.

### 5.20.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`jobID`

ID of job or subjob whose vnodes are to be released.

Format for a job:

`<sequence number>.<server name>`

Format for a subjob:

`<sequence number>[<index>].<server name>`

`vnode_list`

List of vnode names separated by plus signs ("").

If `vnode_list` is a null pointer, this specifies that all the vnodes assigned to the job that are not on the primary execution host are to be released.

`extend`

Character string for extensions to command. Not currently used.

### 5.20.4 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.20.5 See Also

[pbs\\_connect](#)

## 5.21 pbs\_rerunjob

requeue a PBS batch job

### 5.21.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_rerunjob(int connect, char *jobID, char *extend)
```

### 5.21.2 Description

Issues a batch request to requeue a batch job, job array, subjob, or range of subjobs.

Generates a *Rerun Job* (14) batch request and sends it to the server over the connection specified by `connect`.

You cannot requeue a job that is marked as not rerunnable (the `Rerunable` attribute is *False*).

### 5.21.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection handle over which to send batch request to server.

`jobID`

ID of job to be requeued.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

Format for a subjob:

`<sequence number>[<index>].<server name>`

Format for a range of subjobs:

`<sequence number>[<index start>-<index end>].<server name>`

`extend`

Character string for extensions to command. Not currently used.

### 5.21.4 Return Value

The routine returns 0 (zero) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.21.5 See Also

[qrerun](#), [pbs\\_connect](#)

---

## 5.22 pbs\_rlsjob

release a hold on a PBS batch job

### 5.22.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_rlsjob(int connect, char *jobID, char *hold_type, char *extend)
```

### 5.22.2 Description

Issues a batch request to release a hold on a job or job array.

Generates a *Release Job* (13) batch request and sends it to the server over the connection specified by `connect`.

### 5.22.3 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection over which to send batch request to server.

`jobID`

ID of job which is to have a hold released.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

`hold_type`

Type of hold to remove from job or job array. Valid values are defined in `pbs_ifl.h`. If `hold_type` is a null pointer or points to a null string, PBS removes a *User* hold from the job or job array.

`extend`

Character string for extensions to command. Not currently used.

### 5.22.4 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

### 5.22.5 See Also

[qhold](#), [qrls](#), [pbs\\_connect](#), [pbs\\_holdjob](#)

## 5.23 pbs\_runjob

run a PBS batch job

### 5.23.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_runjob(int connect, char *jobID, char *location, char *extend)
```

### 5.23.2 Description

Issues a batch request to run a batch job.

Generates a *Run Job* (15) batch request and sends it to the server over the connection specified by `connect`.

If no file stagein is required, the server replies when the job has started execution. If file stagein is required, the server replies when staging is started.

### 5.23.3 Required Privilege

You must have Operator or Administrator privilege to use this command.

### 5.23.4 Arguments

`connect`

Return value of `pbs_connect ( )`. Specifies connection handle over which to send batch request to server.

`jobID`

ID of job to run.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[<server name>]`

`location`

Location where job should run, and optionally resources to use. Same as `qrun -H`:

`-H <vnode specification without resources>`

The *vnode specification without resources* has this format:

`(<vchunk>)[+(<vchunk>) ...]`

where *vchunk* has the format

`<vnode name>[+<vnode name> ...]`

Example:

`-H (VnodeA+VnodeB)+(VnodeC)`

PBS applies one requested chunk from the job's selection directive in round-robin fashion to each *vchunk* in the list. Each *vchunk* must be sufficient to run the job's corresponding chunk, otherwise the job may not execute correctly.

**-H <vnode specification with resources>**

The *vnode specification with resources* has this format:

(<vchunk>)[+(<vchunk>) ...]

where *vchunk* has the format

<vnode name>:<vnode resources>[+<vnode name>:<vnode resources> ...]

and where *vnode resources* has the format

<resource name>=<value>[:<resource name>=<value> ...]

Example:

`-H (VnodeA:mem=100kb:ncpus=1) +(VnodeB:mem=100kb:ncpus=2+VnodeC:mem=100kb)`

PBS creates a new selection directive from the *vnode specification with resources*, using it instead of the original specification from the user. Any single resource specification results in the job's original selection directive being ignored. Each *vchunk* must be sufficient to run the job's corresponding chunk, otherwise the job may not execute correctly.

If the job being run requests `-l place=exclhost`, take extra care to satisfy the `exclhost` request. Make sure that if any vnodes are from a multi-vnoded host, all vnodes from that host are allocated. Otherwise those vnodes can be allocated to other jobs.

**extend**

Character string for extensions to command. Not currently used.

## 5.23.5 Return Value

The routine returns 0 (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

## 5.23.6 See Also

[qrun](#), [pbs\\_asyruntimejob](#), [pbs\\_connect](#)

## 5.24 pbs\_selectjob

select PBS batch jobs according to specified criteria

### 5.24.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char **pbs_selectjob(int connect, struct attropl *criteria_list, char *extend)
```

### 5.24.2 Description

`pbs_selectjob()` issues a batch request to select jobs that meet specified criteria, and returns an array of job IDs that meet the specified criteria.

This command generates a *Select Jobs* (16) batch request and sends it to the server over the connection handle specified by `connect`.

By default, `pbs_selectjob()` returns all batch jobs for which the user is authorized to query status. You filter the jobs by specifying values for job attributes and resources. You send a linked list of attributes with associated values and operators. Job attributes are listed in [“Job Attributes” on page 328 of the PBS Professional Reference Guide](#).

Returns a list of jobs that meet all specified criteria.

### 5.24.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`criteria_list`

Pointer to a list of attributes to use as selection criteria. Each attribute is described in an `attropl` structure, defined in `pbs_ifl.h` as:

```
struct attropl {
 struct attropl *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

If `criteria_list` itself is null, you are not using attributes or resources as selection criteria.

`extend`

Character string where you can specify limits or extensions of your search.

#### 5.24.3.1 Members of attropl Structure

`next`

Points to next attribute in list. A null pointer terminates the list.

`name`

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**op**

Defines the operator in the logical expression:

*<existing value> <operator> <specified limit>*

Jobs for which the logical expression evaluates to *True* are selected.

For this command, op can be *EQ, NE, GE, GT, LE, LT*.

## 5.24.4 Querying States

You can select jobs in more than one state using a single request, by listing all states you want returned. For example, to get jobs in *Held* and *Waiting* states:

- Fill in `criteria_list->name` with “*job\_state*”
- Fill in `criteria_list->value` with “*HW*” for *Held* and *Waiting*

## 5.24.5 Extending Your Query

You can use the following characters in the `extend` parameter:

**T, t**

Extends query to include subjobs. Job arrays are not included.

**x**

Extends query to include finished and moved jobs.

### 5.24.5.1 Querying Finished and Moved Jobs

To get information on finished or moved jobs, as well as current jobs, add an 'x' character to the `extend` parameter (set one character to be the 'x' character). For example:

```
pbs_selectjob (..., ..., <extend characters>) ...
```

To get information on finished jobs only:

- Add the 'x' character to the `extend` parameter
- Fill in `criteria_list->name` with “*ATTR\_state*”
- Fill in `criteria_list->value` with “*FM*” for *Finished* and *Moved*

Subjobs are not considered finished until the parent array job is finished.

### 5.24.5.2 Querying Job Arrays and Subjobs

To query only job arrays (not jobs or subjobs):

- Fill in `criteria_list->name` with “*array*”
- Fill in `criteria_list->value` with “*True*”

To query only job arrays and subjobs (not jobs):

- Fill in `criteria_list->name` with “*array*”
- Fill in `criteria_list->value` with “*True*”
- Add the ‘*T*’ or ‘*t*’ character to the `extend` parameter

To query only jobs and subjobs (not job arrays), add the ‘*T*’ or ‘*t*’ character to the `extend` parameter.

## 5.24.6 Return Value

The return value is a pointer to a null-terminated array of character pointers. Each character pointer in the array points to a character string which is a job ID in the form:

*<sequence number>.<server>@<server>*

If no jobs met the criteria, the first pointer in the array is null.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

## 5.24.7 Cleanup Required

The returned array of character pointers is `malloc()`’ed by `pbs_selectjob()`. When the array is no longer needed, you must free it via a call to `free()`.

## 5.24.8 See Also

[pbs\\_alterjob](#), [pbs\\_connect](#), [qselect](#)

## 5.25 pbs\_selstat

get status of selected PBS batch jobs

### 5.25.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
struct batch_status *pbs_selstat(int connect, struct attropl *criteria_list, struct attrl *output_attrbs, char *extend)
```

### 5.25.2 Description

Issues a batch request to get the status of jobs which meet the specified criteria.

Generates a *Select Status* (51) batch request and sends it to the server over the connection specified by `connect`.

Returns a list of `batch_status` structures for jobs that meet the selection criteria.

This function is a combination of `pbs_selectjob()` and `pbs_statjob()`.

By default this gives status for all jobs for which you are authorized to query status. You can filter the results by specifying selection criteria.

### 5.25.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`criteria_list`

Pointer to a list of selection criteria, which are attributes and resources with required values. If this list is null, you are not filtering your results via selection criteria. Each attribute or resource is described in an `attropl` structure, defined in `pbs_ifl.h` as:

```
struct attropl {
 struct attropl *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

If `criteria_list` itself is null, you are not using attributes or resources as selection criteria.

`output_attrbs`

Pointer to a list of attributes to return. If this list is null, all attributes are returned. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

**extend**

Character string where you can specify limits or extensions of your selection.

### 5.25.3.1 Members of attropi Structure

**next**

Points to next attribute in list. A null pointer terminates the list.

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource. For parameterized limit attributes, this string contains all parameters for the attribute.

**op**

Specifies the test to be applied to the attribute or resource. The operators are EQ, NE, GE, GT, LE, LT.

### 5.25.3.2 Members of attri Structure

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource. Should always be null.

**next**

Points to next attribute in list. A null pointer terminates the list.

## 5.25.4 Querying States

You can select jobs in more than one state using a single request, by listing all states you want returned. For example, to get jobs in *Held* and *Waiting* states:

- Fill in `criteria_list->name` with “*job\_state*”
- Fill in `criteria_list->value` with “*HW*” for *Held* and *Waiting*

## 5.25.5 Extending Your Query

You can use the following characters in the **extend** parameter:

**T, t**

Extends query to include subjobs. Job arrays are not included.

**x**

Extends query to include finished and moved jobs.

### 5.25.5.1 Querying Finished and Moved Jobs

To get information on finished or moved jobs, as well as current jobs, add an 'X' character to the `extend` parameter (set one character to be the 'X' character). For example:

```
pbs_selstat (..., ..., <extend characters>) ...
```

To get information on finished jobs only:

- Add the 'x' character to the `extend` parameter
- Fill in `criteria_list->name` with “*ATTR\_state*”
- Fill in `criteria_list->value` with “*FM*” for *Finished* and *Moved*

For example:

```
criteria_list->name = ATTR_state;
criteria_list->value = "FM";
criteria_list->op = EQ;
pbs_selstat (..., criteria_list, ..., extend) ...
```

Subjobs are not considered finished until the parent array job is finished.

### 5.25.5.2 Querying Job Arrays and Subjobs

To query only job arrays (not jobs or subjobs):

- Fill in `criteria_list->name` with “*array*”
- Fill in `criteria_list->value` with “*True*”

To query only job arrays and subjobs (not jobs):

- Fill in `criteria_list->name` with “*array*”
- Fill in `criteria_list->value` with “*True*”
- Add the 'T' or 't' character to the `extend` parameter

To query only jobs and subjobs (not job arrays), add the 'T' or 't' character to the `extend` parameter.

## 5.25.6 Return Value

Returns a pointer to a list of `batch_status` structures for jobs that meet the selection criteria. If no jobs meet the criteria or can be queried for status, returns the null pointer.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.25.6.1 The batch\_status Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

### 5.25.7 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

### 5.25.8 See Also

[qselect](#), [qstat](#), [pbs\\_connect](#), [pbs\\_selectjob](#), [pbs\\_statfree](#), [pbs\\_statjob](#)

## 5.26 pbs\_sigjob

send a signal to a PBS batch job

### 5.26.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_sigjob(int connect, char *jobID, char *signal, char *extend)
```

### 5.26.2 Description

Issues a batch request to send a signal to a batch job.

Generates a *Signal Job* (18) batch request and sends it to the server over the connection specified by `connect`.

You can send a signal to a job, job array, subjob, or range of subjobs.

The batch server sends the job the specified signal.

The job must be in the running or suspended state.

### 5.26.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`jobID`

ID of job to be signaled.

Format for a job:

`<sequence number>.<server name>`

Format for a job array:

`<sequence number>[.<server name>`

Format for a subjob:

`<sequence number>[<index>].<server name>`

Format for a range of subjobs:

`<sequence number>[<index start>-<index end>].<server name>`

`signal`

Name of signal to send to job. Can be alphabetic, with or without SIG prefix. Can be signal number.

The following special signals are all lower-case, and have no associated signal number:

**admin-suspend**

Suspends a job and puts its vnodes into the *maintenance* state. The job is put into the *S* state and its processes are suspended.

**admin-resume**

Resumes a job that was suspended using the *admin-suspend* signal, without waiting for scheduler. Cannot be used on jobs that were suspended with the *suspend* signal. When the last admin-suspended job has been admin-resumed, the vnode leaves the maintenance state.

**suspend**

Suspends specified job(s). Job goes into *suspended (S)* state.

**resume**

Marks specified job(s) for resumption by scheduler when there are sufficient resources. Cannot be used on jobs that were suspended with the *admin\_suspend* signal.

If the signal is not recognized on the execution host, no signal is sent and an error is returned.

**extend**

Character string for extensions to command. Not currently used.

## 5.26.4 Return Value

The routine returns *0* (*zero*) on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

## 5.26.5 See Also

[qsig](#), [pbs\\_connect](#)

## 5.27 pbs\_statfree

free a PBS status object

### 5.27.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

### 5.27.2 Description

Frees the specified PBS status object returned by PBS API routines such as `pbs_statque()`, `pbs_statserver()`, `pbs_stathook()`, etc.

### 5.27.3 Arguments

`psj`

Pointer to the `batch_status` structure to be freed.

#### 5.27.3.1 The batch\_status Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attrs;
 char *text;
}
```

### 5.27.4 Return Value

No return value.

## 5.28 pbs\_stathost

get status of PBS execution host(s)

### 5.28.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_stathost(int connect, char *target, struct attrl *output_attrls, char *extend)
```

### 5.28.2 Description

Issues a batch request to get the status of PBS execution hosts.

Generates a *Status Node* (58) batch request and sends it to the server over the connection specified by `connect`.

Returns specified attributes or all attributes of specified execution host or all execution hosts. If an execution host has multiple vnodes, this command reports aggregated information from the vnodes for that host.

### 5.28.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`target`

Name of execution host whose attributes are to be reported. If this argument is a null pointer or points to a null string, returns attributes of all execution hosts known to the server.

`output_attrls`

Pointer to a list of attributes to return. If this argument is null, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

#### 5.28.3.1 Members of attrl Structure

`name`

Points to a string containing the name of the attribute.

`resource`

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, `resource` should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**next**

Points to next attribute in list. A null pointer terminates the list.

## 5.28.4 Return Value

Returns a pointer to a list of `batch_status` structures describing the execution host(s).

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.28.4.1 The `batch_status` Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.28.5 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

## 5.28.6 See Also

[qstat](#), [pbs\\_connect](#), [pbs\\_statfree](#)

## 5.29 pbs\_statjob

get status of PBS batch jobs

### 5.29.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statjob(int connect, char *ID, struct attrl *output_attribs, char *extend)
```

### 5.29.2 Description

Issues a batch request to get the status of a specified batch job, a list of batch jobs, or the batch jobs at a queue or server.

Generates a *Status Job* (19) batch request and sends it to the server over the connection specified by `connect`.

You can query status of jobs, job arrays, subjobs, and ranges of subjobs.

Queries all specified jobs that the user is authorized to query.

### 5.29.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`ID`

Job ID, list of job IDs, queue, server, or null.

If `ID` is a null pointer or points to a null string, gets status of jobs at connected server.

Format for a job:

```
<sequence number>.<server name>
```

Format for a job array:

```
<sequence number>[<index>].<server name>
```

Format for a subjob:

```
<sequence number>[<index>].<server name>
```

Format for a range of subjobs:

```
<sequence number>[<index start>-<index end>].<server name>
```

Format for a list of jobs: comma-separated list of job IDs in a single string. White space is ignored. No limit on length:

```
"<job ID>,<job ID>,<job ID>, ..."
```

Format for a queue:

```
<queue name>@<server name>
```

Format for a server:

```
<server name>
```

**output\_attrbs**

Pointer to a list of attributes to return. If this list is null, all attributes are returned. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

**extend**

Character string where you can specify limits or extensions of your search. Order of characters is not important.

**5.29.3.1 Members of attrl Structure****name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, `resource` should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**next**

Points to next attribute in list. A null pointer terminates the list.

**5.29.4 Querying Job Arrays and Subjobs**

You can query status of job arrays and their subjobs, or just the parent job arrays only.

To query status of job arrays and their subjobs, include the job array IDs in the `ID` argument, and include the `'f'` character in the `extend` argument. The function returns the status of each parent job array followed by status of each subjob in that job array.

To query status of one or more parent job arrays only, but not their subjobs, include their job IDs in the `ID` argument, but do not include anything in the `extend` argument.

**5.29.5 Querying the Jobs at a Queue or Server**

To query status of all jobs at a queue, give the queue name in the `ID` argument.

To query status of all jobs at a server, give the server name in the `ID` argument. If you give a null `ID` argument, the function queries the default server.

**5.29.6 Extending Your Query**

You can use the following characters in the `extend` parameter:

**T, t**

Extends query to include subjobs. Job arrays are not included.

---

X

Extends query to include finished and moved jobs.

### 5.29.6.1 Querying Finished and Moved Jobs

To get status for finished or moved jobs, as well as current jobs, add an 'x' character to the `extend` parameter (set one character to be the 'x' character). For example:

```
pbs_statjob (..., ..., <extend characters>) ...
```

Subjobs are not considered finished until the parent array job is finished.

### 5.29.7 Return Values

For a single job, if the job can be queried, returns a pointer to a `batch_status` structure containing the status of the specified job. If the job cannot be queried, returns a NULL pointer, and `pbs_errno` is set to an error number indicating the reason the job could not be queried.

For a list of jobs, if any of the specified jobs can be queried, returns a pointer to a `batch_status` structure containing the status of all the queryable jobs. If none of the jobs can be queried, returns a NULL pointer, and `pbs_errno` is set to the error number that indicates the reason that the last job in the list could not be queried.

For a queue, if the queue exists, returns a pointer to a `batch_status` structure containing the status of all the queryable jobs in the queue. If the queue does not exist, returns a NULL pointer, and `pbs_errno` is set to `PBSE_UNKQUE (15018)`. If the queue exists but contains no queryable jobs, returns a NULL pointer, and `pbs_errno` is set to `PBSE_NONE (0)`.

When querying a server, the connection to the server is already established by `pbs_connect()`. If there are jobs at the server, returns a pointer to a `batch_status` structure containing the status of all the queryable jobs at the server. If the server does not contain any queryable jobs, returns a NULL pointer, and `pbs_errno` is set to `PBSE_NONE (0)`.

#### 5.29.7.1 The batch\_status Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

### 5.29.8 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

### 5.29.9 See Also

[qstat](#), [pbs\\_connect](#)

## 5.30 pbs\_statnode

get status of PBS execution host(s)

### 5.30.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statnode(int connect, char *target, struct attrl *output_attris, char *extend)
```

### 5.30.2 Description

Issues a batch request to get the status of PBS execution hosts.

Generates a *Status Node* (58) batch request and sends it to the server over the connection specified by `connect`.

Returns specified attributes or all attributes of specified execution host or all execution hosts. If an execution host has multiple vnodes, this command reports aggregated information from the vnodes for that host.

Identical to `pbs_stathost()`; retained for backward compatibility.

### 5.30.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`target`

Name of execution host whose attributes are to be reported. If this argument is null, returns attributes of all execution hosts known to the server.

`output_attris`

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

#### 5.30.3.1 Members of attrl Structure

`name`

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**next**

Points to next attribute in list. A null pointer terminates the list.

## 5.30.4 Return Value

Returns a pointer to a list of **batch\_status** structures describing the host(s).

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer **pbs\_errno**.

### 5.30.4.1 The **batch\_status** Structure

The **batch\_status** structure is defined in **pbs\_ifl.h** as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.30.5 Cleanup

You must free the list of **batch\_status** structures when no longer needed, by calling **pbs\_statfree()**.

## 5.30.6 See Also

## 5.31 pbs\_statque

get status of PBS queue(s)

### 5.31.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
struct batch_status *pbs_statque(int connect, char *target, struct attrl *output_attris, char *extend)
```

### 5.31.2 Description

Issues a batch request to get the status of PBS queues.

Generates a *Status Queue* (20) batch request and sends it to the server over the connection specified by `connect`.

Returns specified attributes or all attributes of specified queue or all queues.

### 5.31.3 Arguments

**connect**

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

**target**

Name of queue whose attributes are to be reported. If this argument is null, returns attributes of all queues known to the server.

**output\_attris**

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

**extend**

Character string for extensions to command. Not currently used.

#### 5.31.3.1 Members of attrl Structure

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, `resource` should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

next

Points to next attribute in list. A null pointer terminates the list.

## 5.31.4 Return Value

Returns a pointer to a list of `batch_status` structures describing the queue(s).

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.31.4.1 The `batch_status` Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.31.5 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

## 5.31.6 See Also

## 5.32 pbs\_statresv

get status of PBS reservation(s)

### 5.32.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statresv(int connect, char *target, struct attrl *output_attribs, char *extend)
```

### 5.32.2 Description

Issues a batch request to get the status of PBS reservation(s).

Generates a *Status Reservation* (71) batch request and sends it to the server over the connection specified by `connect`.

Returns specified attributes or all attributes of specified reservation or all reservations.

### 5.32.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`target`

ID of reservation whose attributes are to be reported. If this argument is a null pointer or points to a null string, returns attributes of all reservations the user is authorized to query.

Format for advance reservation:

*R*<sequence number>.<server name>

Format for standing reservation:

*S*<sequence number>.<server name>

Format for maintenance reservation:

*M*<sequence number>.<server name>

`output_attribs`

Pointer to a list of attributes to return. If this argument is null, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

---

### 5.32.3.1 Members of attrl Structure

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**next**

Points to next attribute in list. A null pointer terminates the list.

### 5.32.4 Return Value

Returns a pointer to a list of **batch\_status** structures describing the reservation(s).

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer **pbs\_errno**.

#### 5.32.4.1 The batch\_status Structure

The **batch\_status** structure is defined in **pbs\_ifl.h** as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

### 5.32.5 Cleanup

You must free the list of **batch\_status** structures when no longer needed, by calling **pbs\_statfree()**.

## 5.33 pbs\_statrsc

get status of PBS resources

### 5.33.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statrsc(int connect, char *rescname, struct attrl *output_attrbs, char *extend)
```

### 5.33.2 Description

Issues a batch request to query and return the status of a specified resource, or a set of resources at a server.

Generates a *Status Resource* (82) batch request and sends it to the server over the connection specified by `connect`.

### 5.33.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`rescname`

Name of resource to be queried. If this is null, queries all resources at the server.

`output_attrbs`

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

#### 5.33.3.1 Members of attrl Structure

`name`

Points to a string containing the name of the attribute.

`resource`

Points to a string containing the name of a resource. Should be a null pointer.

`value`

Points to a string containing the value of the attribute or resource. Should always be a pointer to a null string.

`next`

Points to next attribute in list. A null pointer terminates the list.

---

## 5.33.4 Querying Resources at Server

Use the `pbs_connect ( )` command to get a connection handle at the server.

To query all resources at the server, pass a null pointer as the name of the resource.

## 5.33.5 Return Value

For a single resource, if the resource can be queried, returns a pointer to a `batch_status` structure containing the status of the specified resource.

If the resource cannot be queried, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

When querying a server, the connection to the server is already established by `pbs_connect ( )`. If there are resources at the server, returns a pointer to a `batch_status` structure describing the queryable resource(s) at the server.

In the unlikely event that the server does not contain any queryable resources because the user is unprivileged and all resources are marked as invisible (the `i` flag is set), returns a NULL pointer, and `pbs_errno` is set to `PBSE_NONE (0)`.

### 5.33.5.1 The batch\_status Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.33.6 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree ( )`.

## 5.33.7 See Also

## 5.34 pbs\_statsched

get status of PBS schedulers

### 5.34.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statsched(int connect, struct attrl *output_attribs, char *extend)
```

### 5.34.2 Description

Issues a batch request to get the status of the PBS schedulers.

Generates a *Status Scheduler (81)* batch request and sends it to the server over the connection specified by `connect`.

This command returns status of the default scheduler and all multischeds.

### 5.34.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`output_attribs`

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

#### 5.34.3.1 Members of attrl Structure

`name`

Points to a string containing the name of the attribute.

`resource`

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, `resource` should be a null pointer.

`value`

Points to a string containing the value of the attribute or resource. Should always be a pointer to a null string.

`next`

Points to next attribute in list. A null pointer terminates the list.

---

## 5.34.4 Return Value

Returns a pointer to a list of `batch_status` structures describing the default scheduler and all multischeds.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.34.4.1 The `batch_status` Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.34.5 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

## 5.34.6 See Also

## 5.35 pbs\_statserver

get status of a PBS batch server

### 5.35.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statserver(int connect, struct attrl *output_attrbs, char *extend)
```

### 5.35.2 Description

Issues a batch request to get the status of a batch server.

Generates a *Status Server* (21) batch request and sends it to the server over the connection specified by `connect`.

### 5.35.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`output_attrbs`

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

`extend`

Character string for extensions to command. Not currently used.

#### 5.35.3.1 Members of attrl Structure

`name`

Points to a string containing the name of the attribute.

`resource`

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, `resource` should be a null pointer.

`value`

Points to a string containing the value of the attribute or resource. Should always be a pointer to a null string.

`next`

Points to next attribute in list. A null pointer terminates the list.

## 5.35.4 Return Value

Returns a pointer to a `batch_status` structure describing the server.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.35.4.1 The `batch_status` Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 5.35.5 Cleanup

You must free the `batch_status` structure when no longer needed, by calling `pbs_statfree()`.

## 5.35.6 See Also

## 5.36 pbs\_statvnode

get status of PBS vnode(s) on execution hosts

### 5.36.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
void pbs_statfree(struct batch_status *psj)
```

```
struct batch_status *pbs_statvnode(int connect, char *target, struct attrl *output_attrls, char *extend)
```

### 5.36.2 Description

Issues a batch request to get the status of PBS vnodes on execution hosts.

Generates a *Status Node* (58) batch request and sends it to the server over the connection specified by **connect**.

Returns specified attributes or all attributes of specified execution host vnode or all execution host vnodes.

### 5.36.3 Arguments

**connect**

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

**target**

Name of execution host vnode whose attributes are to be reported. If this argument is null, returns attributes of all execution host vnodes known to the server.

**output\_attrls**

Pointer to a list of attributes to return. If this argument is a null pointer or points to a null string, returns all attributes. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

**extend**

Character string for extensions to command. Not currently used.

#### 5.36.3.1 Members of attrl Structure

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**next**

Points to next attribute in list. A null pointer terminates the list.

## 5.36.4 Return Value

Returns a pointer to a list of `batch_status` structures describing the vnode(s).

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

### 5.36.4.1 The `batch_status` Structure

The `batch_status` structure is defined in `pbs_ifl.h` as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attrs;
 char *text;
}
```

## 5.36.5 Cleanup

You must free the list of `batch_status` structures when no longer needed, by calling `pbs_statfree()`.

## 5.37 pbs\_submit

submit a PBS batch job

### 5.37.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_submit(int connect, struct attropi *attrib_list, char *jobscript, char *destqueue, char *extend)
```

### 5.37.2 Description

Issues a batch request to submit a new batch job.

Generates a *Queue Job* (1) batch request and sends it to the server over the connection specified by `connect`.

Submits job to specified queue at connected server, or if no queue is specified, to default queue at connected server.

### 5.37.3 Arguments

**connect**

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

**attrib\_list**

Pointer to a list of attributes explicitly requested for job. Each attribute is described in an `attropi` structure, defined in `pbs_ifl.h` as:

```
struct attropi {
 struct attropi *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

For any attribute that is not specified or that is a null pointer, PBS takes the default action for that attribute. The default action is to assign the default value or to not pass the attribute with the job; the action depends on the attribute.

**jobscript**

Pointer to path to job script. Can be absolute or relative. Relative path begins with the directory where the user submits the job.

If null pointer or pointer to null string, no script is passed with job.

**destqueue**

Pointer to name of destination queue at connected server. If this is a null pointer or points to a null string, the job is submitted to the default queue at the connected server.

**extend**

Character string for extensions to command. Not currently used.

---

### 5.37.3.1 Members of attropi Structure

**next**

Points to next attribute in list. A null pointer terminates the list.

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**op**

Operation to perform on the attribute or resource. In this command, the only allowed operator is SET.

### 5.37.4 Return Value

Returns a pointer to a character string containing the job ID assigned by the server.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer **pbs\_errno**.

### 5.37.5 Cleanup

The space for the job ID returned by **pbs\_submit()** is allocated by **pbs\_submit()**. Free it via a call to **free()** when you no longer need it.

## 5.38 pbs\_submit\_resv

submit a PBS reservation

### 5.38.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
char *pbs_submit_resv(int connect, struct attropl *attrib_list, char *extend)
```

### 5.38.2 Description

Issues a batch request to submit a new reservation.

Generates a *Submit Reservation* (70) batch request and sends it to the server over the connection specified by `connect`.

Returns a pointer to the reservation ID.

### 5.38.3 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection over which to send batch request to server.

`attrib_list`

Pointer to a list of attributes to set, with values. Each attribute is described in an `attropl` structure, defined in `pbs_ifl.h` as:

```
struct attropl {
 struct attropl *next;
 char *name;
 char *resource;
 char *value;
 enum batch_op op;
};
```

For any attribute that is not specified or that is a null pointer, PBS takes the default action for that attribute. The default action is to assign the default value or to not pass the attribute with the reservation; the action depends on the attribute.

`extend`

Character string for extensions to command. Not currently used.

#### 5.38.3.1 Members of attropl Structure

`next`

Points to next attribute in list. A null pointer terminates the list.

`name`

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Points to a string containing the value of the attribute or resource.

**op**

Operator. The only allowed operator for this function is SET.

## 5.38.4 Return Value

Returns a pointer to a character string containing the reservation ID assigned by the server.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer `pbs_errno`.

## 5.38.5 Cleanup

The space for the reservation ID returned by `pbs_submit_resv()` is allocated by `pbs_submit_resv()`. Free it via a call to `free()` when you no longer need it.

## 5.39 pbs\_terminate

shut down a PBS batch server

### 5.39.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
int pbs_terminate(int connect, int manner, char *extend)
```

### 5.39.2 Description

Issues a batch request to shut down a batch server.

Generates a *Server Shutdown* (17) batch request and sends it to the server over the connection specified by `connect`.

The `pbs_terminate()` command exits after the server has completed its shutdown procedure.

### 5.39.3 Required Privilege

You must have Operator or Manager privilege to run this command.

### 5.39.4 Arguments

`connect`

Return value of `pbs_connect()`. Specifies connection handle over which to send batch request to server.

`manner`

Manner in which to shut down server. The available manners are defined in `pbs_ifl.h`. Valid values: *SHUT\_IMMEDIATE*, *SHUT\_DELAY*, *SHUT\_QUICK*. See [“qterm” on page 233 of the PBS Professional Reference Guide](#) for information on manner in which to shut down server.

`extend`

Character string for extensions to command. Not currently used.

### 5.39.5 Return Value

The routine returns *0 (zero)* on success.

If an error occurred, the routine returns a non-zero exit value, and the error number is available in the global integer `pbs_errno`.

 char *host;
 int port;
int tm_finalize()

```

## 6.2.2 Description

These functions provide a partial implementation of the task management interface part of the PSCHED API. In PBS, MoM provides the task manager functions. This library opens a tcp socket to the MoM running on the local host and sends and receives messages using the DIS protocol (described in the PBS IDS). The tm interface can only be used by a process within a PBS job.

The PSCHED Task Management API description used to create this library was committed to paper on November 15, 1996 and was given the version number 0.1. Changes may have taken place since that time which are not reflected in this library.

The API description uses several data types that it purposefully does not define. This was done so an implementation would not be confined in the way it was written. For this specific work, the definitions follow:

```

typedef int tm_node_id; /* job-relative node id */
#define TM_ERROR_NODE ((tm_node_id)-1)
typedef int tm_event_t; /* > 0 for real events */
#define TM_NULL_EVENT ((tm_event_t)0)
#define TM_ERROR_EVENT ((tm_event_t)-1)
typedef unsigned long tm_task_id;
#define TM_NULL_TASK (tm_task_id)0

```

There are a number of error values defined as well: TM\_SUCCESS, TM\_ESYSTEM, TM\_ENOEVENT, TM\_ENOTCONNECTED, TM\_EUNKNOWNCMD, TM\_ENOTIMPLEMENTED, TM\_EBADENVIRONMENT, TM\_ENOTFOUND.

tm\_init() initializes the library by opening a socket to the MoM on the local host and sending a TM\_INIT message, then waiting for the reply. The info parameter has no use and is included to conform with the PSCHED document. The roots pointer will contain valid data after the function returns and has the following structure:

```

struct tm_roots {

```

```

tm_task_id tm_me;
tm_task_id tm_parent;
int tm_nnodes;
int tm_ntasks;
int tm_taskpoolid;
tm_task_id *tm_tasklist;
};

```

`tm_me` The task id of this calling task.

`tm_parent` The task id of the task which spawned this task or `TM_NULL_TASK` if the calling task is the initial task started by PBS.

`tm_nnodes` The number of nodes allocated to the job.

`tm_ntasks` This will always be 0 for PBS.

`tm_taskpoolid` PBS does not support task pools so this will always be -1.

`tm_tasklist` This will be NULL for PBS.

The `tm_ntasks`, `tm_taskpoolid` and `tm_tasklist` fields are not filled with data specified by the PSCHED document. PBS does not support task pools and, at this time, does not return information about current running tasks from `tm_init`. There is a separate call to get information for current running tasks called `tm_taskinfo` which is described below. The return value from `tm_init` is `TM_SUCCESS` if the library initialization was successful, or an error is returned otherwise.

`tm_nodeinfo()` places a pointer to a malloc'ed array of `tm_node_id`'s in the pointer pointed at by `list`. The order of the `tm_node_id`'s in `list` is the same as that specified to MoM in the "exec\_host" attribute. The int pointed to by `nnodes` contains the number of nodes allocated to the job. This is information that is returned during initialization and does not require communication with MoM. If `tm_init` has not been called, `TM_ESYSTEM` is returned, otherwise `TM_SUCCESS` is returned.

`tm_poll()` is the function which will retrieve information about the task management system to locations specified when other routines request an action take place. The bookkeeping for this is done by generating an event for each action. When the task manager (MoM) sends a message that an action is complete, the event is reported by `tm_poll` and information is placed where the caller requested it. The argument `poll_event` is meant to be used to request a specific event. This implementation does not use it and it must be set to `TM_NULL_EVENT` or an error is returned. Upon return, the argument `result_event` will contain a valid event number or `TM_ERROR_EVENT` on error. If `wait` is zero and there are no events to report, `result_event` is set to `TM_NULL_EVENT`. If `wait` is non-zero and there are no events to report, the function will block waiting for an event. If no local error takes place, `TM_SUCCESS` is returned. If an error is reported by MoM for an event, then the argument `tm_errno` will be set to an error code.

`tm_notify()` is described in the PSCHED documentation, but is not implemented for PBS yet. It will return `TM_ENOTIMPLEMENTED`.

`tm_spawn()` sends a message to MoM to start a new task. The node id of the host to run the task is given by `where`. The parameters `argc`, `argv` and `envp` specify the program to run and its arguments and environment very much like `exec()`. The full path of the program executable must be given by `argv[0]` and the number of elements in the `argv` array is given by `argc`. The array `envp` is NULL terminated. The argument `event` points to a `tm_event_t` variable which is filled in with an event number. When this event is returned by `tm_poll`, the `tm_task_id` pointed to by `tid` will contain the task id of the newly created task.

`tm_kill()` sends a signal specified by `sig` to the task `tid` and puts an event number in the `tm_event_t` pointed to by `event`.

`tm_obit()` creates an event which will be reported when the task `tid` exits. The int pointed to by `obitval` will contain the exit value of the task when the event is reported.

`tm_taskinfo()` returns the list of tasks running on the node specified by `node`. The PSCHED documentation mentions a special ability to retrieve all tasks running in the job. This is not supported by PBS. The argument `tid_list` points to an array of `tm_task_id`'s which contains `list_size` elements. Upon return, `event` will contain an event number. When this event is polled, the `int` pointed to by `ntasks` will contain the number of tasks running on the node and the array will be filled in with `tm_task_id`'s. If `ntasks` is greater than `list_size`, only `list_size` tasks will be returned.

`tm_atnode()` will place the node id where the task `tid` exists in the `tm_node_id` pointed to by `node`.

`tm_rescinfo()` makes a request for a string specifying the resources available on a node given by the argument `node`. The string is returned in the buffer pointed to by `resource` and is terminated by a NUL character unless the number of characters of information is greater than specified by `len`. The resource string PBS returns is formatted as follows:

A space separated set of strings from the `uname` system call. The order of the strings is `sysname`, `nodename`, `release`, `version`, `machine`.

A comma separated set of strings giving the components of the "Resource\_List" attribute of the job, preceded by a colon (:). Each component has the resource name, an equal sign, and the limit value.

`tm_publish()` causes `len` bytes of information pointed at by `info` to be sent to the local MoM to be saved under the name given by `name`.

`tm_subscribe()` returns a copy of the information named by `name` for the task given by `tid`. The argument `info` points to a buffer of size `len` where the information will be returned. The argument `info_len` will be set with the size of the published data. If this is larger than the supplied buffer, the data will have been truncated.

`tm_attach()` commands MoM to create a new PBS "attached task" out of a session running on MoM's host. The `jobid` parameter specifies the job which is to have a new task attached. If it is NULL, the system will try to determine the correct `jobid`. The `cookie` parameter must be NULL. The `pid` parameter must be a non-zero process id for the process which is to be added to the job specified by `jobid`. If `tid` is non-NULL, it will be used to store the task id of the new task. The `host` and `port` parameters specify where to contact MoM. `host` should be NULL. The return value will be 0 if a new task has been successfully created and non-zero on error. The return value will be one of the TM error numbers defined in `tm.h` as follows:

TM\_ESYSTEM MoM cannot be contacted

TM\_ENOTFOUND No matching job was found

TM\_ENOTIMPLEMENTED The call is not implemented/supported

TM\_ESESSION The session specified is already attached

TM\_EUSER The calling user is not permitted to attach

TM\_EOWNER The process owner does not match the job

TM\_ENOPROC The process does not exist

`tm_finalize()` may be called to free any memory in use by the library and close the connection to MoM.

## RM Library

This chapter describes the PBS Resource Monitor library. The RM library contains functions to facilitate communication with the PBS Professional resource monitor. It is set up to make it easy to connect to several resource monitors and handle the network communication efficiently.

### 7.1 RM Library Routines

The following manual pages document the application programming interface provided by the RM library.

## 7.2 openrm, closerm, downrm, configrm, addreq, allreq, getreq, flushreq, activereq, fullresp

resource monitor API

### 7.2.1 Synopsis

```
#include <sys/types.h>
#include <netinet/in.h>
#include <rm.h>
int openrm (host, port)
 char *host;
 unsigned int port;
int closerm (stream)
 int stream;
int downrm (stream)
 int stream;
int configrm (stream, file)
 int stream;
 char *file;
int addreq (stream, line)
 int stream;
 char *line;
int allreq (line)
 char *line;
char *getreq(stream)
 int stream;
int flushreq()
int activereq()
void fullresp(flag)
 int flag;
```

### 7.2.2 Description

The resource monitor library contains functions to facilitate communication with the PBS Professional resource monitor. It is set up to make it easy to connect to several resource monitors and handle the network communication efficiently.

In all these routines, the variable `pbs_errno` will be set when an error is indicated. The lower levels of network protocol are handled by the "Data Is Strings" DIS library and the TPP library.

`configrm()` causes the resource monitor to read the file named. *Deprecated.*

`addreq()` begins a new message to the resource monitor if necessary. Then adds a line to the body of an outstanding command to the resource monitor.

`allreq()` begins, for each stream, a new message to the resource monitor if necessary. Then adds a line to the body of an outstanding command to the resource monitor.

---

`getreq()` finishes and sends any outstanding message to the resource monitor. If `fullresp()` has been called to turn off "full response" mode, the routine searches down the line to find the equal sign just before the response value. The returned string (if it is not NULL) has been allocated by `malloc` and thus `free` must be called when it is no longer needed to prevent memory leaks.

`flushreq()` finishes and sends any outstanding messages to all resource monitors. For each active resource monitor structure, it checks if any outstanding data is waiting to be sent. If there is, it is sent and the internal structure is marked to show "waiting for response".

`fullresp()` turns on, if flag is true, "full response" mode where `getreq()` returns a pointer to the beginning of a line of response. This is the default. If flag is false, the line returned by `getreq()` is just the answer following the equal sign.

`activereq()` Returns the stream number of the next stream with something to read or a negative number (the return from `tpp_poll`) if there is no stream to read.

In order to use any of the above with Windows, initialize the network library and link with `winsock2`. To do this, call `winsock_init()` before calling the function and link against the `ws2_32.lib` library.

`tcp(4P)`, `udp(4P)`

# TCL/tk Interface

As of version 19.4.1, the PBS TCL API is **deprecated**.

The PBS Professional software includes a TCL/tk interface to PBS. Wrapped versions of many of the API calls are compiled into a special version of the TCL shell, called `pbs_tclsh`. (A special version of the tk window shell is also provided, called `pbs_wish`.) This chapter documents the TCL/tk interface to PBS.

The `pbs_tclapi` is a subset of the PBS external API wrapped in a TCL library. This functionality allows the creation of scripts that query the PBS system. Specifically, it permits the user to query the `pbs_server` about the state of PBS, jobs, queues, and nodes, and communicate with `pbs_mom` to get information about the status of running jobs, available resources on nodes, etc.

## 8.1 TCL/tk API Functions

A set of functions to communicate with the PBS server and resource monitor have been added to those normally available with Tcl. All these calls will set the Tcl variable `pbs_errno` to a value to indicate if an error occurred. In all cases, the value "0" means no error. If a call to a Resource Monitor function is made, any error value will come from the system supplied `errno` variable. If the function call communicates with the PBS server, any error value will come from the error number returned by the server. This is the same TCL interface used by the `pbs_tclsh` and `pbs_wish` commands.

Note that the `pbs_tclapi pbsresquery` command, which calls the C API `pbs_resquery`, is **obsolete**. Any attempt to use it will result in a `PBSE_NOSUPPORT` error being returned.

## 8.2 pbs\_tclapi

PBS TCL Application Programming Interface

### 8.2.1 Description

The pbs\_tclapi is a subset of the PBS external API wrapped in a TCL library. This functionality allows the creation of scripts that query the PBS system. Specifically, it permits the user to query the pbs\_server about the state of PBS, jobs, queues, and nodes, and communicate with pbs\_mom to get information about the status of running jobs, available resources on nodes, etc.

### 8.2.2 Usage

A set of functions to communicate with the PBS server and resource monitor have been added to those normally available with Tcl. All these calls will set the Tcl variable "pbs\_errno" to a value to indicate if an error occurred. In all cases, the value "0" means no error. If a call to a Resource Monitor function is made, any error value will come from the system supplied errno variable. If the function call communicates with the PBS Server, any error value will come from the error number returned by the server. This is the same TCL interface used by the pbs\_tclsh and pbs\_wish commands.

`openrm host ?port?`

Creates a connection to the PBS Resource Monitor on host using port as the port number or the standard port for the resource monitor if it is not given. A connection handle is returned. If the open is successful, this will be a non-negative integer. If not, an error occurred.

`closerm connection`

The parameter connection is a handle to a resource monitor which was previously returned from openrm. This connection is closed.

Nothing is returned.

`downrm connection`

Sends a command to the connected resource monitor to shutdown.

Nothing is returned.

`configrm connection filename`

Sends a command to the connected resource monitor to read the configuration file given by filename. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`addreq connection request`

A resource request is sent to the connected resource monitor. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`getreq connection`

One resource request response from the connected resource monitor is returned. If an error occurred or there are no more responses, an empty string is returned.

`allreq request`

A resource request is sent to all connected resource monitors. The number of streams acted upon is returned.

`flushreq`

All resource requests previously sent to all connected resource monitors are flushed out to the network. Nothing is returned.

**activereq**

The connection number of the next stream with something to read is returned. If there is nothing to read from any of the connections, a negative number is returned.

**fullresp flag**

Evaluates flag as a boolean value and sets the response mode used by getreq to full if flag evaluates to "true". The full return from a resource monitor includes the original request followed by an equal sign followed by the response. The default situation is only to return the response following the equal sign. If a script needs to "see" the entire line, this function may be used.

**pbsstatserv**

The server is sent a status request for information about the server itself. If the request succeeds, a list with three elements is returned, otherwise an empty string is returned. The first element is the server's name. The second is a list of attributes. The third is the "text" associated with the server (usually blank).

**pbsstatjob**

The server is sent a status request for information about the all jobs resident within the server. If the request succeeds, a list is returned, otherwise an empty string is returned. The list contains an entry for each job. Each element is a list with three elements. The first is the job's jobid. The second is a list of attributes. The attribute names which specify resources will have a name of the form "Resource\_List:name" where "name" is the resource name. The third is the "text" associated with the job (usually blank).

**pbsstatque**

The server is sent a status request for information about all queues resident within the server. If the request succeeds, a list is returned, otherwise an empty string is returned. The list contains an entry for each queue. Each element is a list with three elements. This first is the queue's name. The second is a list of attributes similar to pbsstatjob. The third is the "text" associated with the queue (usually blank).

**pbsstatnode**

The server is sent a status request for information about all nodes defined within the server. If the request succeeds, a list is returned, otherwise an empty string is returned. The list contains an entry for each node. Each element is a list with three elements. This first is the node's name. The second is a list of attributes similar to pbsstatjob. The third is the "text" associated with the node (usually blank).

**pbsselstat**

The server is sent a status request for information about the all runnable jobs resident within the server. If the request succeeds, a list similar to pbsstatjob is returned, otherwise an empty string is returned.

**pbsrunjob jobid ?location?**

Run the job given by jobid at the location given by location. If location is not given, the default location is used. If this is successful, a "0" is returned, otherwise, "-1" is returned.

**pbsasyrunjob jobid ?location?**

Run the job given by jobid at the location given by location without waiting for a positive response that the job has actually started. If location is not given, the default location is used. If this is successful, a "0" is returned, otherwise, "-1" is returned.

**pbsrerunjob jobid**

Re-runs the job given by jobid. If this is successful, a "0" is returned, otherwise, "-1" is returned.

**pbsdeljob jobid**

Delete the job given by jobid. If this is successful, a "0" is returned, otherwise, "-1" is returned.

**pbsholdjob jobid**

Place a hold on the job given by jobid. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsmovejob jobid ?location?`

Move the job given by `jobid` to the location given by `location`. If `location` is not given, the default location is used. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsqenable queue`

Set the "enabled" attribute for the queue given by `queue` to true. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsqdisable queue`

Set the "enabled" attribute for the queue given by `queue` to false. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsqstart queue`

Set the "started" attribute for the queue given by `queue` to true. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsqstop queue`

Set the "started" attribute for the queue given by `queue` to false. If this is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsalterjob jobid attribute_list`

Alter the attributes for a job specified by `jobid`. The parameter `attribute_list` is the list of attributes to be altered. There can be more than one. Each attribute consists of a list of three elements. The first is the name, the second the resource and the third is the new value. If the alter is successful, a "0" is returned, otherwise, "-1" is returned.

`pbsresquery resource_list`

Deprecated. Obtain information about the resources specified by `resource_list`. This will be a list of strings. If the request succeeds, a list with the same number of elements as `resource_list` is returned. Each element in this list will be a list with four numbers. The numbers specify available, allocated, reserved, and down in that order.

`pbsconnect ?server?`

Make a connection to the named server or the default server if a parameter is not given. Only one connection to a server is allowed at any one time.

`pbsdisconnect`

Disconnect from the currently connected server.

The above Tcl functions use PBS interface library calls for communication with the server and the PBS resource monitor library to communicate with `pbs_mom`.

`datetime ?day? ?time?`

The number of arguments used determine the type of date to be calculated. With no arguments, the current POSIX date is returned. This is an integer in seconds.

With one argument there are two possible formats. The first is a 12 (or more) character string specifying a complete date in the following format:

`YYMMDDhhmmss`

All characters must be digits. The year (YY) is given by the first two (or more) characters and is the number of years since 1900. The month (MM) is the number of the month [01-12]. The day (DD) is the day of the month [01-32]. The hour (hh) is the hour of the day [00-23]. The minute (mm) is minutes after the hour [00-59]. The second (ss) is seconds after the minute [00-59]. The POSIX date for the given date/time is returned.

The second option with one argument is a relative time. The format for this is

`HH:MM:SS`

---

With hours (HH), minutes (MM) and seconds (SS) being separated by colons ":". The number returned in this case will be the number of seconds in the interval specified, not an absolute POSIX date.

With two arguments a relative date is calculated. The first argument specifies a day of the week and must be one of the following strings: "Sun", "Mon", "Tue", "Wed", "Thr", "Fri", or "Sat". The second argument is a relative time as given above. The POSIX date calculated will be the day of the week given which follows the current day, and the time given in the second argument. For example, if the current day was Monday, and the two arguments were "Fri" and "04:30:00", the date calculated would be the POSIX date for the Friday following the current Monday, at four-thirty in the morning. If the day specified and the current day are the same, the current day is used, not the day one week later.

strftime format time

This function calls the POSIX function strftime(). It requires two arguments. The first is a format string. The format conventions are the same as those for the POSIX function strftime(). The second argument is POSIX calendar time in second as returned by datetime. It returns a string based on the format given. This gives the ability to extract information about a time, or format it for printing.

logmsg tag message

This function calls the internal PBS function log\_err(). It will cause a log message to be written to the scheduler's log file. The tag specifies a function name or other word used to identify the area where the message is generated. The message is the string to be logged.

# 9

# Hooks

This chapter describes the PBS hook APIs. For more information on hooks, see the PBS Professional Administrator's Guide.

## 9.1 Introduction

A hook is a block of Python code that is triggered in response to queueing a job, modifying a job, moving a job, running a job, submitting a PBS reservation, MoM receiving a job, MoM starting a job, MoM killing a job, a job finishing, and MoM cleaning up a job. Each hook can *accept* (allow) or *reject* (prevent) the action that triggers it. The hook can modify the input parameters given for the action. The hook can also make calls to functions external to PBS. PBS provides an interface for use by hooks. This interface allows hooks to read and/or modify things such as job and server attributes, the server, queues, and the event that triggered the hook.

The Administrator creates any desired hooks.

This chapter contains the following man pages:

- `pbs_module`(7B)
- `pbs_stathook`(3B)

See the following additional man pages:

- `qmgr`(1B)
- `qsub`(1B)
- `qmove`(1B)
- `qalter`(1B)
- `pbs_rsub`(1B)
- `pbs_manager`(3B)

## 9.2 How Hooks Work

### 9.2.1 Hook Contents and Permissions

A hook contains a Python script. The script is evaluated by a Python 3 or later interpreter, embedded in PBS.

Hooks have a default Linux umask of 022. File permissions are inherited from the current working directory of the hook script.

### 9.2.2 Accepting and Rejecting Actions

The hook script always accepts the current event request action unless an unhandled exception occurs in the script, a hook alarm timeout is triggered or there's an explicit call to `pbs.event().reject()`.

### 9.2.3 Exceptions

A hook script can catch an exception and evaluate whether or not to accept or reject the event action. In this example, while referencing the non-existent attribute `pbs.event().job.interactive`, an exception is triggered, but the event action is still accepted:

```
...
try:
 e = pbs.event()
 if e.job.interactive:
 e.reject("Interactive jobs not allowed")
except SystemExit:
 pass
except:
 e.accept()
```

### 9.2.4 Unsupported Interfaces and Uses

Site hooks which read, write, close, or alter `stdin`, `stdout`, or `stderr`, are not supported. Hooks which use any interfaces other than those described are unsupported.

## 9.3 Interface to Hooks

Two PBS APIs are used with hooks. These are `pbs_manager()` and `pbs_stathook()`. The `pbs` module provides a Python interface to PBS.

### 9.3.1 The `pbs` Module

Hooks have access to a special module called “`pbs`”, which contains functions that perform PBS-related actions. This module must be explicitly loaded by the hook writer via the call “`import pbs`”.

The *pbs module* provides an interface to PBS and the hook environment. The interface is made up of Python objects, which have attributes and methods. You can operate on these objects using Python code.

#### 9.3.1.1 Description of `pbs` Module

## 9.4 pbs\_module

The interface is made up of Python objects, which have attributes and methods. You can operate on these objects using Python code. For a description of each object, see the PBS Professional Administrator's Guide.

### 9.4.0.1 pbs Module Objects

See ["The pbs Module" on page 76 in the PBS Professional Hooks Guide](#).

### 9.4.0.2 pbs Module Global Attribute Creation Methods

See ["PBS Types and Their Methods" on page 143 in the PBS Professional Hooks Guide](#).

### 9.4.0.3 Attributes and Resources

See ["Using Attributes and Resources in Hooks" on page 44 in the PBS Professional Hooks Guide](#).

### 9.4.0.4 Exceptions

See ["Table of Exceptions" on page 43 in the PBS Professional Hooks Guide](#) and ["Hook Alarm Calls and Unhandled Exceptions" on page 43 in the PBS Professional Hooks Guide](#).

### 9.4.0.5 See Also

The *PBS Professional Administrator's Guide*, `pbs_hook_attributes(7B)`, `pbs_resources(7B)`, `qmgr(1B)`

## 9.4.1 The pbs\_manager() API

The `pbs_manager()` API is described in ["pbs\\_manager" on page 41](#).

The `pbs_manager()` API contains the following:

- An `obj_name` called "hook" defined as `MGR_OBJ_HOOK`, for use with non-built-in hooks
- An `obj_name` called "pbshook" defined as `MGR_OBJ_PBS_HOOK`, for use with built-in hooks.
- The following hook commands, which operate only on hook objects:

#### **MGR\_CMD\_IMPORT**

This command is used for loading the hook script contents into a hook.

#### **MGR\_CMD\_EXPORT**

This command is used for dumping to a file the contents of a hook script.

The parameters to `MGR_CMD_IMPORT` and `MGR_CMD_EXPORT` are specified via the `attrib` parameter of `pbs_manager()`.

For `MGR_CMD_IMPORT`, specify `attropl` "name" as "content-type", "content-encoding", and "input-file" along with the corresponding "value" and an "op" of SET.

For `MGR_CMD_EXPORT`, specify `attropl` "name" as "content-type", "content-encoding", and "output-file" along with the corresponding "value" and an "op" of SET.

Functions `MGR_CMD_IMPORT`, `MGR_CMD_EXPORT`, and `MGR_OBJ_HOOK` are used only with hooks, and therefore require root privilege on the server host.

When `obj_name` is `MGR_OBJ_PBS_HOOK`, the only allowed options for command are `MGR_CMD_SET`, `MGR_CMD_UNSET`, `MGR_CMD_IMPORT`, and `MGR_CMD_EXPORT`.

If `MGR_CMD_IMPORT` or `MGR_CMD_EXPORT` is specified when `obj_name` is `MGR_OBJ_PBS_HOOK`, the attribute `content-type` must be “application/x-config”.

### 9.4.1.1 Troubleshooting

You can use `pbs_geterrmsg()` to determine the last error message received from the `pbs_manager()` call. For instance, with a `MGR_OBJ_PBS_HOOK` where command is either `MGR_CMD_IMPORT` or `MGR_CMD_EXPORT`, but attribute `content-type` is not “application/x-config”, `pbs_geterrmsg()` returns:

```
"<content-type> must be application/x-config"
```

If an unrecognized hook configuration file suffix is given, whether for `MGR_OBJ_HOOK` or `MGR_OBJ_PBS_HOOK`, `pbs_geterrmsg()` returns:

```
"<input-file> contains an invalid suffix, should be one of: .json .py .txt .xml .ini"
```

If the hook configuration file failed to be precompiled by PBS, `pbs_geterrmsg()` shows:

```
"Failed to validate config file, hook '<hook_name>' config file not overwritten"
```

### 9.4.1.2 Privilege for Hooks

To run, hooks require root privilege on Linux, and local Administrators privilege on Windows.

### 9.4.1.3 Examples of Using pbs\_manager()

Example 9-1: The following:

```
qmgr -c 'import hook hook1 application/x-python base64 hello.py.b64'
```

is programmatically equivalent to:

```
static struct attrop1 imp_attribs[] = {
 { "content-type",
 (char *)0,
 "application/x-python",
 SET,
 (struct attrop1 *)&imp_attribs[1]
 },
 { "content-encoding",
 (char *)0,
 "base64",
 SET,
 (struct attrop1 *)&imp_attribs[2]},
 { "input-file",
 (char *)0,
 "hello.py.b64",
 SET,
 (struct attrop1 *)0
 }
};

pbs_manager(con, MGR_CMD_IMPORT, MGR_OBJ_HOOK, "hook1", &imp_attribs[0], NULL);
```

Example 9-2: The following:

```
qmgr -c 'export hook hook1 application/x-python default hello.py'
```

is programmatically equivalent to:

```
static struct attrop1 exp_attribs[] = {
 { "content-type",
 (char *)0,
 "application/x-python",
 SET,
 (struct attrop1 *)&exp_attribs[1]},
 { "content-encoding",
 (char *)0,
 "default",
 SET,
 (struct attrop1 *)&exp_attribs[2]},
 { "output-file",
 (char *)0,
 "hello.py",
 SET,
 (struct attrop1 *)0
 }
};
```

```
 }
};
```

```
pbs_manager(con, MGR_CMD_EXPORT, MGR_OBJ_HOOK, "hook1", &exp_attribs[0], NULL);
```

Example 9-3: The following:

```
qmgr -c 'import pbshook hook1 application/x-config default hello.json'
```

is programmatically equivalent to:

```
static struct attrop1 imp_attribs[] = {
 { "content-type",
 (char *)0,
 "application/x-config",
 SET,
 (struct attrop1 *)&imp_attribs[1]},
 { "content-encoding",
 (char *)0,
 "default",
 SET,
 (struct attrop1 *)&imp_attribs[2]},
 { "input-file",
 (char *)0,
 "hello.json",
 < SET,
 (struct attrop1 *)0
 }
};
```

```
pbs_manager(con, MGR_CMD_IMPORT, MGR_OBJ_PBS_HOOK, "hook1", &imp_attribs[0], NULL);
```

Example 9-4: The following:

```
qmgr -c 'export pbshook hook1 application/x-config default hello.json'
```

is programmatically equivalent to:

```
static struct attrop1 exp_attribs[] = {
 { "content-type",
 (char *)0,
 "application/x-config",
 SET,
 (struct attrop1 *)&exp_attribs[1]},
 { "content-encoding",
 (char *)0,
 "default",
 SET,
 (struct attrop1 *)&exp_attribs[2]},
 { "output-file",
 (char *)0,
 "hello.json",
 SET,
 (struct attrop1 *)0
 }
};
```

```
pbs_manager(con, MGR_CMD_EXPORT,
MGR_OBJ_PBS_HOOK, "hook1", &exp_attribs[0], NULL);
```

## 9.4.2 The `pbs_stathook()` API

The PBS API called “`pbs_stathook()`” is used to get attributes and values for site hooks and built-in hooks.

The prototype for `pbs_stathook()` is as follows:

```
struct batch_status *pbs_stathook(int connect, char *hook_name, struct attrl *attrib, char
 *extend)
```

To query status for site hooks:

The call to `pbs_stathook()` causes a `PBS_BATCH_StatusHook` request to be sent to the server. In reply, the PBS server returns a batch reply status of object type `MGR_OBJ_HOOK` listing the attributes and values that were requested relating to a particular hook or all hooks of type `HOOK_SITE`. Leave the extend value blank.

To query status for built-in hooks:

Pass `PBS_HOOK` as the extend value. The server returns a batch reply status of object type `MGR_OBJ_PBS_HOOK`.

### 9.4.2.1 Example of Using `pbs_stathook()`

To list all site hooks using `qmgr`:

```
qmgr -c "list hook"
```

To list all site hooks using the `pbs_stathook()` API:

```
pbs_stathook()
```

The result is the same. For example, if there are two site hooks, `c3` and `c36`:

```
Hook c3
 type = site
 enabled = true
 event = queuejob, modifyjob
 user = pbsadmin
 alarm = 30
 order = 1
```

```
Hook c36
 type = site
 enabled = true
 event = resvsub
 user = pbsadmin
 alarm = 30
 order = 1
```

## 9.5 pbs\_stathook(3B)

get status information about PBS site hooks

### 9.5.1 Synopsis

```
#include <pbs_error.h>
```

```
#include <pbs_ifl.h>
```

```
struct batch_status *pbs_stathook(int connect, char *hook_id, struct attrl *output_attrls, char *extend)
```

```
void pbs_statfree(struct batch_status *psj)
```

### 9.5.2 Description

Issues a batch request to get the status of a specified site hook or a set of site hooks at the current server.

Generates a *Status Hook* batch request and sends it to the server over the connection specified by *connect*.

#### 9.5.2.1 Required Privilege

This API can be executed only by root on the local server host.

### 9.5.3 Arguments

**connect**

Return value of `pbs_connect ( )`. Specifies connection handle over which to send batch request to server.

**hook\_id**

Hook name, null string, or null pointer.

If *hook\_id* specifies a name, the attribute-value list for that hook is returned.

If *hook\_id* is a null string or a null pointer, the status of all hooks at the current server is returned.

**output\_attrls**

Pointer to a list of attributes to return. If this list is null, all attributes are returned. Each attribute is described in an `attrl` structure, defined in `pbs_ifl.h` as:

```
struct attrl {
 char *name;
 char *resource;
 char *value;
 struct attrl *next;
};
```

**extend**

Character string where you can specify limits or extensions of your selection.

#### 9.5.3.1 Members of attrl Structure

**name**

Points to a string containing the name of the attribute.

**resource**

Points to a string containing the name of a resource. Used only when the specified attribute contains resource information. Otherwise, **resource** should be a null pointer.

**value**

Should always be a pointer to a null string.

**next**

Points to next attribute in list. A null pointer terminates the list.

## 9.5.4 Return Value

Returns a pointer to a list of **batch\_status** structures for the specified site hook. If no site hook can be queried for status, returns the null pointer.

If an error occurred, the routine returns a null pointer, and the error number is available in the global integer **pbs\_errno**.

### 9.5.4.1 The batch\_status Structure

The **batch\_status** structure is defined in **pbs\_if1.h** as

```
struct batch_status {
 struct batch_status *next;
 char *name;
 struct attrl *attribs;
 char *text;
}
```

## 9.5.5 Cleanup

You must free the list of **batch\_status** structures when no longer needed, by calling **pbs\_statfree()**.

## 9.5.6 Error Messages

The following error message is returned by the **pbs\_geterrormsg()** API after calling **pbs\_manager()** operating on a hook object, with the **MGR\_CMD\_IMPORT** command, with “content-type” of “application/x-config”:

“Failed to validate config file, hook 'submit' config file not overwritten”

If the input config file given is of unrecognized suffix, then the following message is returned by the **pbs\_geterrormsg()** API after calling **pbs\_manager()** operating on a hook object, **MGR\_CMD\_IMPORT** command with “content-type” of “application/x-config”:

“<input-file> contains an invalid suffix, should be one of: .json .py .txt .xml .ini”

If you specify an unknown hook event, **pbs\_geterrormsg()** returns the following after calling **pbs\_manager()**:

invalid argument (<bad\_event>) to event. Should be one or more of:  
 queuejob,modifyjob,resvsub,movjob,runjob,provision,execjob\_begin,execjob\_prologue,execjob\_epilogue,execjob\_preterm,execjob\_end,exechost\_periodic,execjob\_launch,exechost\_startup or ""  
 for no event

If you specify an invalid value for a hook’s debug attribute, the following error message appears in **qmgr**’s **stderr** and is returned by **pbs\_geterrormsg()** after calling **pbs\_manager()**:

“unexpected value '<bad\_val>' must be (not case sensitive) true|t|y|1|false|f|n|0”

---

A runjob hook cannot set the value of a `Resource_List` member other than those listed in ["Table: Reading & Setting Built-in Job Resources in Hooks" on page 60 in the PBS Professional Hooks Guide](#). Setting any of the wrong resources results in the following:

- The hook request is rejected
- The following message is the output from calling `pbs_geterrmsg()` after the failed `pbs_runjob()`:  
" request rejected by filter hook: '<hook name>' hook failed to set job's  
Resource\_List.<resc\_name> = <resc\_value> (not allowed)"

## 9.5.7 See Also

# Custom Authentication and Encryption Library APIs

This chapter describes LibAuth, which contains APIs you can use to create your own custom authentication or encryption library.

Call the `pbs_auth_set_config` API first before calling any other LibAuth API.

## Table of Authentication and Encryption APIs

9.1	<code>pbs_auth_set_config</code> .....	120
9.2	<code>pbs_auth_create_ctx</code> .....	121
9.3	<code>pbs_auth_destroy_ctx</code> .....	123
9.4	<code>pbs_auth_get_userinfo</code> .....	124
9.5	<code>pbs_auth_process_handshake_data</code> .....	126
9.6	<code>pbs_auth_encrypt_data</code> .....	128
9.7	<code>pbs_auth_decrypt_data</code> .....	129

## 10.1 pbs\_auth\_set\_config

specify configuration for authentication library

### 10.1.1 Synopsis

```
void pbs_auth_set_config(const pbs_auth_config_t *auth_config)
```

### 10.1.2 Description

Specifies configuration for the authentication library. Use this to specify logging method, where to find required credentials, etc.

Call this API first before calling any other LibAuth API.

### 10.1.3 Arguments

`const pbs_auth_config_t *auth_config`

Pointer to a configuration structure

### 10.1.4 Configuration Structure

```
typedef struct pbs_auth_config {
```

```
 char *pbs_home_path;
```

Path to PBS\_HOME directory (aka same value as PBS\_HOME in pbs.conf). This must be a null-terminated string.

```
 char *pbs_exec_path;
```

Path to PBS\_EXEC directory (aka same value as PBS\_EXEC in pbs.conf). This must be a null-terminated string.

```
 char *auth_method;
```

Name of authentication method (aka same value as PBS\_AUTH\_METHOD in pbs.conf). This must be a null-terminated string.

```
 char *encrypt_method;
```

Name of encryption method (aka same value as PBS\_ENCRYPT\_METHOD in pbs.conf). This must be a null-terminated string

```
 void (*logfunc)(int type, int objclass, int severity, const char *objname, const char *text);
```

Function pointer to the logging method with the same signature as log\_event from Liblog.

With this, the user of the authentication library can redirect logs from the authentication library into respective log files or stderr in case no log files.

If func is set to NULL then logs will be written to stderr (if available, else no logging at all).

```
} pbs_auth_config_t;
```

### 10.1.5 Return Value

None return value

## 10.2 pbs\_auth\_create\_ctx

create authentication context

### 10.2.1 Synopsis

```
int pbs_auth_create_ctx(void **ctx, int mode, int conn_type, char *hostname)
```

### 10.2.2 Description

Creates an authentication context for a given mode and connection type. Context is used by other LibAuth APIs for authentication, encryption, and decryption of data.

### 10.2.3 Arguments

void \*\*ctx

Pointer to auth context to be created

int mode

Specifies type of context to be created. Should be one of *AUTH\_CLIENT* or *AUTH\_SERVER*.

Use *AUTH\_CLIENT* for client-side (who is initiating authentication) context

Use *AUTH\_SERVER* for server-side (who is authenticating incoming user/connection) context

```
enum AUTH_ROLE {
 AUTH_ROLE_UNKNOWN = 0,
 AUTH_CLIENT,
 AUTH_SERVER,
 AUTH_ROLE_LAST
};
```

int conn\_type

Specifies type of connection is for context to be created. Should be one of *AUTH\_USER\_CONN* or *AUTH\_SERVICE\_CONN*

Use *AUTH\_USER\_CONN* for user-oriented connection (such as when PBS client is connecting to PBS server)

Use *AUTH\_SERVICE\_CONN* for service-oriented connection (such as when PBS MoM is connecting to PBS server via PBS comm)

```
enum AUTH_CONN_TYPE {
 AUTH_USER_CONN = 0,
 AUTH_SERVICE_CONN
};
```

char \*hostname

The null-terminated hostname of another authenticating party

### 10.2.4 Return Value

Integer.

0

On Success

1

On Failure

### 10.2.5 Cleanup

When a context created using this API is no longer required, destroy it via `auth_destroy_ctx`.

## 10.3 pbs\_auth\_destroy\_ctx

destroy an authentication context created using `auth_create_ctx`

### 10.3.1 Synopsis

```
void pbs_auth_destroy_ctx(void *ctx)
```

### 10.3.2 Description

Destroys the authentication context created using `auth_create_ctx`

### 10.3.3 Arguments

`void *ctx`

Pointer to authentication context to be destroyed

### 10.3.4 Return Value

No return value

## 10.4 pbs\_auth\_get\_userinfo

extract username with its realm, and hostname of connecting party from authentication context

### 10.4.1 Synopsis

```
int pbs_auth_get_userinfo(void *ctx, char **user, char **host, char **realm)
```

### 10.4.2 Description

Extracts username with its realm, and hostname of the connecting party from the given authentication context.

The extracted user, host, and realm values are null-terminated strings.

This API is mostly useful for authenticating on the server side to get information about an authenticating client.

The authenticating server can use this information from the auth library to match against the actual username/realm/hostname provided by the connecting party.

### 10.4.3 Arguments

`void *ctx`

Pointer to auth context from which information will be extracted

`char **user`

Pointer to a buffer in which this API will write the user name

`char **host`

Pointer to a buffer in which this API will write hostname

`char **realm`

Pointer to a buffer in which this API will write the realm

### 10.4.4 Return Value

Integer

0

On success

1

On failure

### 10.4.5 Cleanup

When the returned user, host, and realm are no longer required, free them using `free()`, since they use allocated heap memory.

### 10.4.6 Example

This example shows what the values of user, host, and realm will be. Let's use an example with GSS/Kerberos authentication, where the authentication client hostname is "xyz.abc.com", the username is "test", and in the Kerberos configuration, the domain realm is "PBSPRO". When the client authenticates to the server using the Kerberos authentication method, it is authenticated as "test@PBSPRO", and this API returns user = test, host = xyz.abc.com, and realm = PBSPRO.

## 10.5 pbs\_auth\_process\_handshake\_data

handle and generate handshakes, and generate handshake data

### 10.5.1 Synopsis

```
int pbs_auth_process_handshake_data(void *ctx, void *data_in, size_t len_in, void **data_out, size_t *len_out, int
 *is_handshake_done)
```

### 10.5.2 Description

Process incoming handshake data and do the handshake. If required generate handshake data which to be sent to another party. If there is no incoming data then initiate a handshake and generate initial handshake data to be sent to the authentication server.

### 10.5.3 Arguments

**void \*ctx**

Pointer to authentication context for which handshake is happening

**void \*data\_in**

Incoming handshake data to process, if any. A NULL value indicates that this API should initiate a handshake and generate initial handshake data to be sent to the authentication server.

**size\_t len\_in**

Length of incoming handshake data, if any, else 0

**void \*\*data\_out**

Outgoing handshake data to be sent to another authentication party.

A NULL value indicates that the handshake is completed and no further data needs to be sent.

When this API returns 1 (failure), data\_out contains the error message.

**size\_t \*len\_out**

Length of outgoing handshake/auth error data, if any, else 0

**int \*is\_handshake\_done**

Indicates whether handshake is completed or not.

0 means that the handshake is not completed.

1 means that the handshake is completed.

### 10.5.4 Return Value

Integer

0

On success

1

On failure

On failure, the value of data\_out is the error data/message, to be sent to another authentication party as authentication error data.

## 10.5.5 Cleanup

When the returned `data_out` (if any) is no longer required, free it using `free()`, since it uses allocated heap memory.

## 10.6 pbs\_auth\_encrypt\_data

encrypt data using specified authentication context

### 10.6.1 Synopsis

```
int pbs_auth_encrypt_data(void *ctx, void *data_in, size_t len_in, void **data_out, size_t *len_out)
```

### 10.6.2 Description

Encrypt given unencrypted data using the specified authentication context.

### 10.6.3 Arguments

`void *ctx`

Pointer to auth context which will be used while encrypting given unencrypted data

`void *data_in`

unencrypted data to encrypt

`size_t len_in`

Length of unencrypted data

`void **data_out`

Encrypted data

`size_t *len_out`

Length of encrypted data

### 10.6.4 Return Value

Integer

0

Success

1

Failure

### 10.6.5 Cleanup

When the returned `data_out` is no longer required, free it using `free()`, since it uses allocated heap memory.

---

## 10.7 pbs\_auth\_decrypt\_data

decrypt data

### 10.7.1 Synopsis

```
int pbs_auth_decrypt_data(void *ctx, void *data_in, size_t len_in, void **data_out, size_t *len_out)
```

### 10.7.2 Description

Decrypt encrypted data using the specified authentication context

### 10.7.3 Arguments

`void *ctx`

Pointer to authentication context which will be used while decrypting given encrypted data

`void *data_in`

Encrypted data to decrypt

`size_t len_in`

Length of encrypted data

`void **data_out`

Unencrypted data

`size_t *len_out`

Length of unencrypted data

### 10.7.4 Return Value

Integer

0

On success

1

On failure

### 10.7.5 Cleanup

When the returned `data_out` is no longer required, free it using `free()`, since it uses allocated heap memory.

# Installing Cloud Bursting Module

## 1.1 Supported Platforms for Cloud

- CentOS 6, 7
- RHEL 6, 7
- SLES 12

## 1.2 Supported Cloud Providers

You must already have an account with one of the supported cloud providers:

- Microsoft Azure
- Amazon Web Services (AWS)
- Google Cloud Platform (GCP)
- Oracle Cloud Platform
- Orange Cloud Flexible Engine
- Open Telekom Cloud (OTC)
- HUAWEI Cloud

---

## 1.3 Prerequisites

- A working PBS complex managed by PBS Professional version 2020.1. The PBS complex can be either of the recommended configurations in [Recommended Configurations](#)
- Altair License Server 14.5 or later
- PBSProNodes v20 license
- docker-ce v19.x or later
  - The root filesystem must be ext3 or ext4, XFS can NOT be used (docker issue)
  - An additional volume could be added to the system using ext3/ext4 and docker configured to use this volume; see [section 1.6, “Configuring a Cloud Head Node in Azure”, on page 6](#) for steps involved.
- Current install procedure assumes Centos or RedHat (requires yum)
- SELinux must be disabled (reboot the system to make this the active config)
- Firewalld must be disabled and stopped
- VPN connection to the cloud you will use
  - Except in the case of a cloud hosted head node.
- Cloud account with:
  - Correct authorizations
  - Budget to run cloud infrastructure.

## 1.4 Recommended Configurations

Head node and service node can be one of either:

- Both on premises
- Both in cloud

Do not put one on premises and one in the cloud.

See [section 1.6, “Configuring a Cloud Head Node in Azure”, on page 6](#).

### 1.4.1 Recommended Configuration for Larger Installations

For larger installations using on premises hosts:

- Hosts on premises for PBS server, scheduler, some MoM daemons, cloud service node
- Head, service, and first N execution nodes are on premises
- Extra execution nodes are burst
- On head node, PBS components running as usual
- On service node
  - Cloud is designed to run in a container
- VPN connection to the cloud you will use

Notes:

- You may not want Docker on the head node, because it may impose too high a load.
- All components are mix-and-match (with Docker restriction).
- The Cloud module may cause too much load to be run on the head node.
- You don't need to configure additional `pbs_comm` daemons for cloud nodes, because cloud can't cause enough throughput to need one.
- For PBS configuration instructions, see the *PBS Professional Administrator's Guide*.

## 1.4.2 Recommended Configuration for Smaller Installations

For smaller installations cloud-only installations where the workload is low enough:

- All PBS components can be hosted in the cloud
- All components can run on the same node
- You can run Docker on the same node as the PBS components

Notes:

- No VPN is required for this configuration.
- See [section 1.6, “Configuring a Cloud Head Node in Azure”, on page 6](#).

## 1.5 Installation Steps

1. Log in as root

2. Install, start, and enable `docker-ce`:

```
yum install -y yum-utils
yum-config-manager --add-repo https://download.docker.com/linux/centos/docker-ce.repo
yum install docker-ce docker-ce-cli containerd.io
systemctl enable docker
systemctl start docker
```

3. Extract the installer to \$home:

```
tar xvfz pbspro-cloud-pbspro-cloud.tar.gz
```

4. If the PBS cloud hook, named “cloud\_hook”, exists, delete it:

```
qmgr -c 'd h cloud_hook'
```

5. Install PBS cloud feature, PBS cloud hook, and Cloud command layer. Execute the installation script: Change directory to `pbspro-cloud-installer` directory:

```
cd pbspro-cloud-installer
./install.sh
```

6. If the Cloud command is already installed please use this command and then retry [5](#):

```
hook/install.sh --type uninstall
```

7. Create an alias to easily use `pkcr`. Type the following all one line:

```
alias pkcr=" docker run -ti --network host --rm -e PBSCLLOUD_VERSION=pbspro-cloud-2020.2
PKR_VERSION=pbspro-cloud-2020.2 -v /run/docker.sock:/run/docker.sock -v /root/kard:/pkcr/kard
pbsclaudio.azurecr.io/pkr:pbspro-cloud-2020.2 pkcr"
```

8. Make sure that relevant services are up and running. Each should have an IP address. See [section 1.8.1, “Sample pkr Output on Startup”, on page 11](#) for sample healthy output reference data for pkr.

**pkcr ps**

9. If hosting a head node in the cloud, use the vendor tools to open access to port 9980 so you can use the Cloud web interface.
10. Go to the Cloud interface in your web browser and log in:
 

`http://<server>:9980/pbspro-cloud/#/login`

  - Login: pbsadmin@altair
  - Password: Altair@123
11. Build your cloud environment. We give an example using Azure, but you can use any of the supported cloud providers. For how to use the various provided clouds, see [Chapter 3, “Using Cloud Provider Services”, on page 59](#).
12. If using Azure: configure a cloud resource group To configure a cloud resource group and network in Azure:
  - a. Follow [section 3.3.3, “Create a Resource Group”, on page 77](#)
  - b. Follow [section 3.3.4, “Create a Virtual Network”, on page 77](#)
13. If using Azure: register Cloud with Azure; see [section 3.3.1, “Register the Cloud Application with Azure”, on page 73](#)
  - a. Use `http://<server>:9980/pbspro-cloud/` for your Cloud service address (App Registration step) where the documentation may point you towards `https://<hostname>:9500/pc/` or similar, and noting that this edition of Cloud is running on http (Azure interface requires https) - this is expected and managed internally in Azure)
  - b. Ensure you configure IAM for your App Registration at the Subscription level (use search to locate Subscription if required) for the subscription containing your Resource Group
  - c. Obtain the relevant keys to register your cloud account in PBS Cloud
14. If using Azure: add a Microsoft Azure account; see [section 3.3.2, “Add a Microsoft Azure Cloud Account”, on page 76](#)
  - a. Connect PBS Cloud to your Azure account
  - b. Wait for status to change to READY in PBS Cloud
15. If using Azure: to build out your cloud infrastructure, including your burst node image, in Azure:
  - a. Follow [section 3.3.5, “Create a Virtual Machine”, on page 78](#)
  - b. Follow [section 3.3.6, “Install the PBS MoM on the VM”, on page 80](#)
  - c. Ensure you install cloud-init in your cloud Virtual Machine before converting it into an image for bursting in the next step (10.7.7)
 

**yum install -y cloud-init**
  - d. Follow [section 3.3.7, “Create an OS Image”, on page 82](#)

16. If using Azure: create an Azure cloud bursting scenario; see [section 3.3.8, “Create an Azure Cloud Bursting Scenario”, on page 83](#)

a. Create a scenario for bursting. Recommended options:

- Give it a short name (all lower case): e.g. hyperburst
- Select Managed Disks
- Select Public IP (To debug burst nodes, deactivate once productionised)
- Suggest using Standard\_A4 image for minimal cost
- Provide a cloud-init script; see [section 2.2.4, “Example of a cloud-init Script for a Linux Virtual Machine”, on page 18](#) for a sample script
- Follow the procedure to create a scenario token and store the token safely (it is lost once you close the window, though you can simply create another if you lose it)

17. This and the rest of the steps are for all cloud providers. Configure the cloud PBS Professional resources. For more information, see [section 2.3, “Configure PBS Professional for Cloud Bursting”, on page 21](#).

```
qmgr -c 'create resource cloud_queue type=boolean'
qmgr -c 'create resource cloud_instance_type type=string'
qmgr -c 'create resource cloud_node_instance_type type=string,flag=h'
qmgr -c 'create resource cloud_min_instances type=long'
qmgr -c 'create resource cloud_max_instances type=long'
qmgr -c 'create resource cloud_provisioned_time type=long,flag=h'
qmgr -c 'create resource lic_signature type=string,flag=h'
qmgr -c 'create resource cloud_node_image type=string,flag=h'
qmgr -c 'create resource cloud_network type=string,flag=h'
qmgr -c 'create resource node_location type=string,flag=h'
qmgr -c 'create resource cloud_max_jobs_check_per_queue type=long'
qmgr -c 'create resource cloud_scenario type=string,flag=h'
qmgr -c 'create resource burst_by_hook type=boolean'
```

18. Update sched\_config to add cloud\_scenario, cloud\_node\_image, cloud\_node\_instance\_type, e.g.

```
resources: "ncpus, mem, arch, host, vnode, netwins, aoe, cloud_scenario, cloud_node_image,
cloud_node_instance_type"
```

19. Reread the sched config file: Either HUP the scheduler or restart PBS

20. Config PBS server limits

```
qmgr -c 'set server resources_available.cloud_min_instances = 0'
qmgr -c 'set server resources_available.cloud_max_instances = 1'
```

21. Create a cloud queue and attach scenario name

This assumes scenario is called hyperburst and you configured Standard\_A4 in the PBS Cloud web interface as instance types, change as appropriate for your configuration options.

```
qmgr -c 'c q cloudq queue_type=execution'
qmgr -c 's q cloudq enabled=t'
qmgr -c 's q cloudq started=t'
qmgr -c 's q cloudq resources_available.cloud_queue = True'
qmgr -c 's q cloudq resources_available.cloud_max_jobs_check_per_queue = 1000'
qmgr -c 's q cloudq resources_available.cloud_scenario=hyperburst'
qmgr -c 's q cloudq resources_available.cloud_instance_type=Standard_A4'
```

- 
22. Configure cloud hook configuration file with scenario details. See [section 2.3.9, “Configure the Cloud Bursting Hook”, on page 35](#). Once configured the changes go live immediately.
  23. Test manual burst of one node from web interface
    - Ensure Public IP is activated in the scenario to allow access to the node for debugging purposes in case there are issues
    - Example: If following [Configuring a Cloud Head Node in Azure](#) for a cloud head node, then if /home fails to mount
    - The cloud-init script may need tuning to make this successful, such as mounting home directory to avoid passwordless `ssh`, or having a directory with all apps on it and mounting that on each cloud compute node; that way you can just update the directory.
    - Typical cycle is burst, check, unburst, modify config/cloud-init, repeat
  24. Enable the cloud hook in PBS:
 

```
qmgr -c 'set hook cloud_hook enabled = true'
```

To check the state of the hook:

```
qmgr -c 'l h cloud_hook'
```
  25. Execute a test job; see [section 4.2, “Sample Job Script: Cloud Job”, on page 139](#)
  26. What does success look like?
    - In output of `qstat` for job, you see “job can never run”
    - Auto bursting is triggered, and the web interface shows a workflow in action
    - The job runs on the burst node
    - The node un-bursts sometime later when it is idle
    - All job outputs are returned successfully prior to unburst

## 1.6 Configuring a Cloud Head Node in Azure

Here we show an example of how to configure a cloud head node using Azure:

1. Create a new VM based on Centos 7, using Rogue Wave Software’s CentOS-based 7.6 image, not an HPC tagged version
  - Use Standard\_D14 instance type for head node (Good price/performance option)
  - Add additional storage: 1000GB SSD to allow an ext4 volume to be added; the Centos image uses XFS filesystem which has a bug with docker
2. Provide a public ssh key for the username “centos” via Azure GUI
 

This is the only default user in this image
3. Once the node is up, use the provided external IP and your private key to connect to it. PuTTY is more robust for connection to cloud than Moba xTerm
4. Unless noted otherwise all the following commands must be run as root. Use `sudo` or the following to switch to the root user:
 

```
sudo su -
```

5. Use `cfdisk` to partition `/dev/sdc` using all space for a single volume. Make absolutely sure that `/dev/sdc` is the right target. The target depends on instance type chosen and how many disks are added; if you followed the procedure exactly this should be correct in this case, but formatting is destructive to data on the disk.

```
cfdisk /dev/sdc
```

- a. Select New
  - b. Select Primary
  - c. Accept Default Size (Should be whole disk)
  - d. Select Write
  - e. Answer yes (You will need to type yes)
  - f. Select Quit
6. Create a filesystem on your drive (ext4 preferred):

```
mkfs -t ext4 /dev/sdc1
```

7. Make a folder to mount your new volume to:

```
mkdir /data
```

8. Set suitable permissions on the folder:

```
chmod 777 /data
```

9. Find UUID from `/dev/disk/by-uuid`, e.g.

```
lrwxrwxrwx 1 root root 10 Apr 1 12:48 640a03fd-aa69-4f8d-98d5-2f0d3d12bb26 -> ../../sdb1
lrwxrwxrwx 1 root root 10 Apr 1 12:48 a505f591-5a7d-424f-a5a1-06dcb72f944c -> ../../sda1
lrwxrwxrwx 1 root root 10 Apr 1 12:48 c6cd262b-3930-48a8-9b21-8981bb479cee -> ../../sdc1
lrwxrwxrwx 1 root root 10 Apr 1 12:48 e0d6ff47-4c69-4a4c-b44a-13ea19d80f96 -> ../../sda2
```

10. Add a line to end of `/etc/fstab` for this mount (Note: ID of `/dev/sdc1` above):

```
UUID=c6cd262b-3930-48a8-9b21-8981bb479cee /data ext4 defaults 0 0
```

11. Mount the new filesystem:

```
mount /data
```

12. Upgrade all system packages to the latest versions:

```
yum upgrade
```

13. Disable SELinux by editing `/etc/selinux/config` and changing, then save:

```
SELINUX=enforcing -> SELINUX=disabled
```

14. Disable and stop `firewalld`

```
systemctl disable firewalld
systemctl stop firewalld
```

15. SELinux is still enforcing, so prevent that. Reboot.

16. Add password to user “centos”:

```
passwd centos
```

17. Log in as centos

18. Create ssh keys for centos and enable passwordless ssh

Accept all the defaults for ssh-keygen step:

```
cd $HOME
ssh-keygen
cd .ssh
cat id_rsa.pub >> authorized_keys
```

19. For a cloud head node, make sure you validate that external ssh still works externally, before you disconnect your first session. If there is an issue with ssh keys, which can be sometimes caused by errors in step [18](#) above, and you disconnect your first session, you could be permanently locked out of your cloud VM. Use ssh from your local machine to your cloud head node to create a second session using your public ssh key. Troubleshoot as required while your first session is still up.

20. Add the key PBS Professional service users:

```
useradd -rm pbsdata; useradd pbsadmin
```

21. Follow steps [17](#), [18](#), and [19](#) for user pbsadmin

22. Install/Start/Enable docker-ce

```
yum install -y yum-utils
yum-config-manager --add-repo https://download.docker.com/linux/centos/docker-ce.repo
yum install docker-ce docker-ce-cli containerd.io
systemctl enable docker
systemctl start docker
```

23. Stop docker:

```
systemctl stop docker
```

24. Move docker data storage to new filesystem mounted on /data

25. Add -g /data/docker \ in file /lib/systemd/system/docker.service. ExecStart should look like this:

```
ExecStart=/usr/bin/dockerd-current ...
--seccomp-profile=/etc/docker/seccomp.json -g /data/docker $OPTIONS ...
$REGISTRIES
```

26. Reread daemon config files:

```
systemctl daemon-reload
```

27. Look in /data/docker; there should be subdirectories for docker data

28. Start docker:

```
systemctl start docker
```

29. Create a repository for PBS Package

```
mkdir /home/centos/software
chown -R centos:centos /home/centos/software
chmod 777 /home/centos/software
```

30. Download all the PBS package modules to your software directory (PBS Professional, Cloud)

31. Install and configure NFS Server to share /home from head node, so you can avoid setting up ssh keys for client nodes and have a convenient mount:

```
yum install nfs-utils
systemctl enable nfs-blkmap
systemctl enable nfs-rquotad
systemctl enable nfs-server
systemctl enable nfs
systemctl start nfs-blkmap
systemctl start nfs-rquotad
systemctl start nfs-server
systemctl start nfs
```

32. Edit /etc/exports to add

```
/home *(rw,sync,no_root_squash,no_all_squash)
```

33. Restart NFS Server:

```
systemctl restart nfs-server
```

34. Add local machine name and IP to /etc/hosts, remove IPv6 loopback, e.g.

```
127.0.0.1 localhost localhost.localdomain localhost4 localhost4.localdomain4
<pbs_server_ip> <pbs_server_hostname>
```

On my system this would be:

```
127.0.0.1 localhost localhost.localdomain localhost4 localhost4.localdomain4
172.17.0.6 myhost
```

35. Follow the *PBS Professional Installation & Upgrade Guide*, the *PBS Professional Administrator's Guide*, and the *PBS Professional Licensing Guide* to install, configure and license PBS Professional

- Set PBS to have MoM running on the head node before first start

36. Run test job and ensure job output is returned without issues (e.g. scp problems)

Sample test script using default workq:

```
#!/bin/bash
#PBS -N testjob
#PBS -j oe
#PBS -m n
#PBS -q workq
#PBS -l select=1:ncpus=2:mem=16mb
#PBS -l walltime=0:10:00
sleeptime=60
cmd="sleep $sleeptime"
echo $cmd
$cmd
Exit
```

37. Optionally enable a few useful config options:

```
qmgr -c 'set server eligible_time_enable = True'
qmgr -c 'set server job_history_enable = True'
qmgr -c 'set server job_history_duration = 72:00:00'
qmgr -c 'set server scheduler_iteration = 30'
qmgr -c 'set server max_job_sequence_id = 999999999'
qmgr -c 'set server job_sort_formula = \"eligible_time + job_priority\"'
```

## 1.7 Sample Cloud Hook Configuration File

Here we show a basic cloud hook configuration file with a single scenario.

You can export and look at the installed PBS cloud hook configuration file:

```
qmgr -c 'export hook cloud_hook application/x-config default' >cloud_hook.json
```

You can edit this file and change its parameters, then read it back in:

```
qmgr -c 'import hook cloud_hook application/x-config default cloud_hook.json'
```

Replace these tokens with the correct information:

<name or IP address of PBS Cloud service>  
 <scenario name> (The name of your cloud bursting scenario)  
 <burst token> (The token you created for your cloud bursting scenario)  
 <cloud image> (The cloud image you created for your cloud bursting scenario)

### 1.7.1 Contents of Sample Cloud Hook Configuration File

```
{
 "pclm_server": "https://<name or IP address of server>:9980/pbspro-cloud/",
 "pclm_no_check_ssl_certificate": true,
 "cloud_min_instances": 0,
 "resources": ["ncpus", "mem", "ngpus"],
 "use_node_hour_license": false,
 "cloud_driver": "PclmDriver",
 "scenario": {
 "<scenario name>": {
 "api_key": "<burst token>",
 "cloud_default_image": "<cloud image>",
 "cloud_max_instances": 10,
 "max_nodes_per_burst": 50,
 "cloud_node_wait_timeout": 180
 }
 }
}
```

---

## 1.8 Command Reference and Sample Output for pkr

We use pkr to manage all the containers in the current kard. In this context that means all the services around the Cloud Bursting feature in PBS Professional. Each service runs in its own container.

To start all pkr services:

```
pkr start
```

### 1.8.1 Sample pkr Output on Startup

```
[root@myhost ~]# pkr start
Starting node-exporter ... done
Starting elasticsearch ... done
Starting mongodb ... done
Starting cadvisor ... done
Starting postgres ... done
Starting rabbitmq ... done
Starting prometheus ... done
Starting bootstrapper-worker1 ... done
Starting bootstrapper-worker ... done
Starting guardian ... done
Starting kibana ... done
Starting logstash ... done
Starting grafana ... done
Starting websocket-bridge ... done
Starting pacioli ... done
Starting notification-center ... done
Starting hubble ... done
Starting mistral-api ... done
Starting keeper ... done
Starting hype ... done
Starting mistral-executor ... done
Starting executor-api ... done
Starting cloudflow ... done
Starting bootstrapper-api ... done
Starting services ... done
Starting ui ... done
```

To stop all pkr services:

```
pkr stop
```

---

## 1.8.2 Sample pkr Output on Stop

```
[root@myhost ~]# pkr stop
Stopping pacioli ... done
Stopping ui ... done
Stopping services ... done
Stopping bootstrapper-api ... done
Stopping cloudflow ... done
Stopping executor-api ... done
Stopping mistral-executor ... done
Stopping hype ... done
Stopping mistral-api ... done
Stopping hubble ... done
Stopping notification-center ... done
Stopping websocket-bridge ... done
Stopping keeper ... done
Stopping guardian ... done
Stopping grafana ... done
Stopping kibana ... done
Stopping logstash ... done
Stopping bootstrapper-worker ... done
Stopping bootstrapper-worker1 ... done
Stopping prometheus ... done
Stopping elasticsearch ... done
Stopping rabbitmq ... done
Stopping mongodb ... done
Stopping postgres ... done
Stopping node-exporter ... done
Stopping cadvisor ... done
```

To list all pkr services:

```
pkr ps
```

---

## 1.8.3 Sample pkr Output while Running

System is running:

```
[root@myhost ~]# pkr ps
- cadvisor:
- elasticsearch: 172.19.0.7
- postgres: 172.19.0.6
- mongodb: 172.19.0.5
- guardian: 172.19.0.13
- keeper: 172.19.0.17
- kibana: 172.19.0.10
- logstash: 172.19.0.14
- hubble: 172.19.0.2
- rabbitmq: 172.19.0.4
- mistral-api: 172.19.0.20
- executor-api: 172.19.0.23
- cloudflow: 172.19.0.24
- mistral-executor: 172.19.0.22
- websocket-bridge: 172.19.0.15
- notification-center: 172.19.0.18
- services: 172.19.0.25
- bootstrapper-api: 172.19.0.21
- pacioli: 172.19.0.19
- bootstrapper-worker1: 172.19.0.12
- bootstrapper-worker: 172.19.0.11
- hype: 172.19.0.16
- node-exporter: 172.19.0.3
- prometheus: 172.19.0.8
- grafana: 172.19.0.9
- ui: 172.19.0.26
```

---

## 1.8.4 Sample pkr Output while Stopped

System is stopped:

```
[root@myhost ~]# pkr ps
- cadvisor: stopped
- elasticsearch: stopped
- postgres: stopped
- mongodb: stopped
- guardian: stopped
- keeper: stopped
- kibana: stopped
- logstash: stopped
- hubble: stopped
- rabbitmq: stopped
- mistral-api: stopped
- executor-api: stopped
- cloudflow: stopped
- mistral-executor: stopped
- websocket-bridge: stopped
- notification-center: stopped
- services: stopped
- bootstrapper-api: stopped
- pacioli: stopped
- bootstrapper-worker1: stopped
- bootstrapper-worker: stopped
- hype: stopped
- node-exporter: stopped
- prometheus: stopped
- grafana: stopped
- ui: stopped
```

## 1.9 Logging into Cloud

To log into Cloud, go to the Cloud interface in your web browser:

`http://<server>:9980/pbspro-cloud/#/login`

# Configuring Cloud Bursting

## 2.1 Introduction to Cloud Bursting

PBS has a cloud bursting capability that allows a PBS complex to handle demand peaks by bursting to a cloud. This ensures that jobs continue to be executed as quickly as possible, without interruption to service.

Jobs are submitted to one or more designated cloud queues, and a server periodic hook monitors the cloud queues, estimates the demand for cloud nodes, and dynamically adjusts the number of nodes by bursting or unbursting as needed.

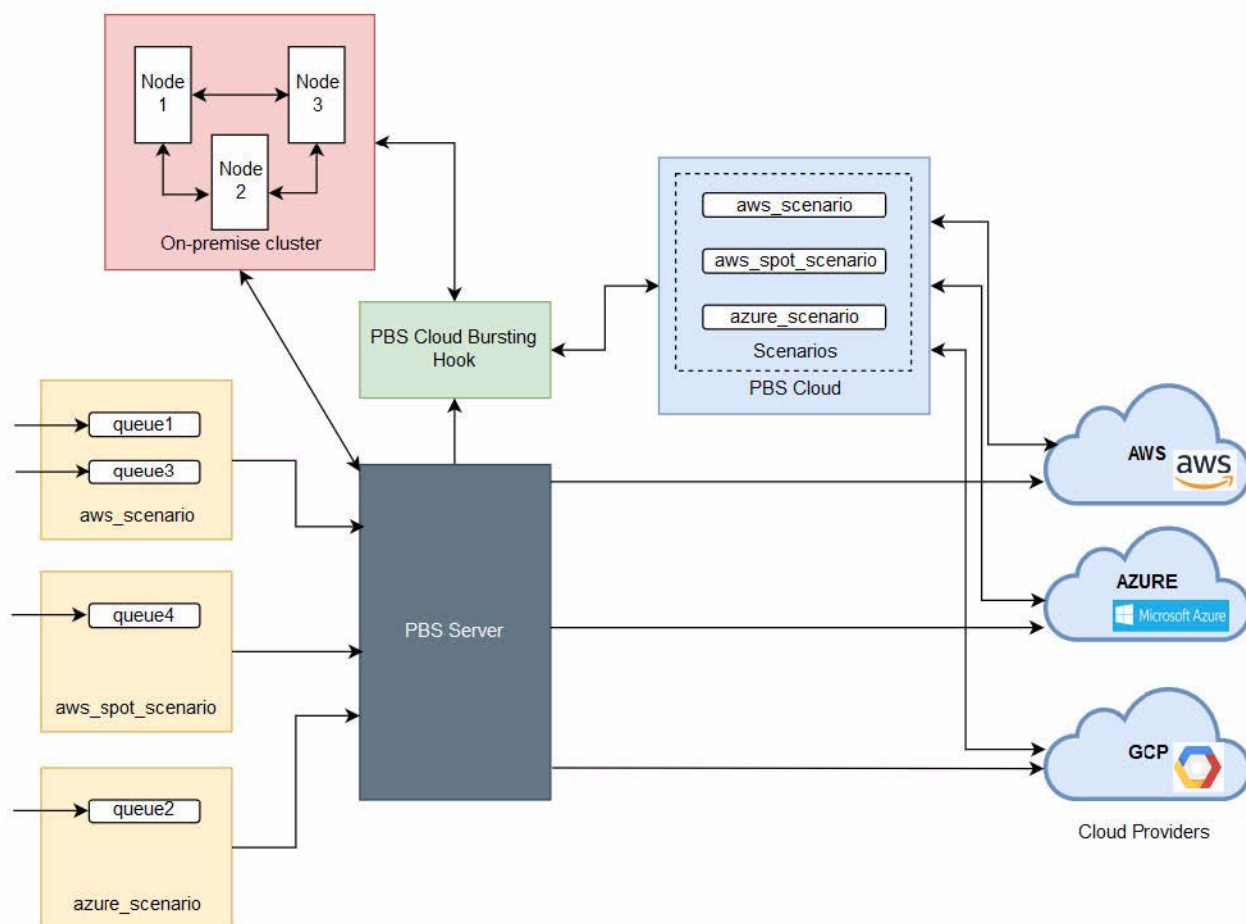

Figure 2-1: Typical Cloud Bursting Setup

---

## 2.1.1 Overview of Configuring Cloud Bursting

You need to do some setup at the cloud provider level before creating a cloud bursting scenario using Cloud. You also need to configure PBS for cloud bursting. The setup is different at each cloud provider. Here's an outline of the steps required:

1. Create a boot script that runs after a cloud node is burst.
2. Create necessary cloud provider components such as a virtual network and a virtual machine.
3. SSH into the cloud provider virtual machine and configure the VM for your site's environment such as installing PBS, mounting file systems, connecting it to the authentication service, installing any applications, etc.
4. Create an image of the virtual machine.
5. Create a bursting scenario with Cloud that provides the necessary cloud provider details required for cloud bursting.
6. Configure PBS cloud bursting custom resources.
7. Create PBS cloud queues.
8. Configure the PBS cloud bursting hook.
9. Enable a bursting scenario.

Steps vary depending on which cloud provider you use.

## 2.1.2 Cloud Bursting Terminology

### **Burst**

The action of adding a node in the cloud, and adding it to the PBS complex.

### **Unburst**

The action of removing a node from both the PBS complex and the cloud.

### **Bursting scenario**

Scenario created in Cloud containing information about resources provided by the cloud service that are used for bursting.

### **Image**

A pre-configured OS image in the cloud from which virtual machines can be instantiated.

### **Instance**

A single virtual machine in a cloud computing environment.

### **Instance type**

Instance characteristics made up of CPU, memory, storage, and networking capacity.

### **api\_key**

Scenario token generated for the bursting scenario. Identifies cloud service provider and controls access to the Cloud cloud bursting APIs.

---

## 2.2 Cloud Bursting Startup Script

### 2.2.1 Introduction

You will want to do some configuration to each cloud nodes after it boots. For example, you may want to install some packages, add users, or start services. You can add a startup script to a bursting scenario that runs when the instance boots, in order to perform automated tasks. Startup scripts can perform many actions, such as installing software, performing updates, turning on services, and any other tasks defined in the script. You can use startup scripts to easily and programmatically customize your cloud instances.

### 2.2.2 Startup Script on Windows Platforms

On Windows platforms, the startup script must be a PowerShell script. The content of the PowerShell script should be enclosed in `<powershell>` and `</powershell>`. Refer to Microsoft documentation for more information about PowerShell.

### 2.2.3 Startup Script on Linux Platforms

On Linux platforms, cloud-init is a utility specifically designed for cloud instance initialization. The cloud-init program is a bootstrapping utility for pre-provisioned disk images that run in virtualized environments, usually cloud-oriented services. Basically, it sets up the server instance to be usable when it's finished booting. You must install cloud-init on your cloud provider VM to simplify the task of configuring your instances on boot. For more information see [cloud-init](#).

The cloud-init utility supports the following input types:

- Shell scripts

The simplest way to configure an instance at boot time is to use a shell script. The shell script must begin with `#!` in order for cloud-init to recognize it as a shell script.

## 2.2.4 Example of a cloud-init Script for a Linux Virtual Machine

In the following, we show examples of actions in a configuration script intended to be run after bursting a node in the cloud; the script includes a description of the purpose for each section. Do not use this as is; make sure you adapt the script to your site.

```
#!/bin/sh
Map PBS server IP address to hostnames via /etc/hosts
echo "/etc/hosts setup"
rm -f /etc/hosts
echo "127.0.0.1 localhost localhost.localdomain localhost4 localhost4.localdomain4" > /etc/hosts
echo "PBS_SERVER_IP_ADDR headnode headnode.DOMAINNAME" >> /etc/hosts

Disable NetworkManager and use network interface
so that it does not overwrite the /etc/resolv.conf file
systemctl disable NetworkManager
systemctl stop NetworkManager
systemctl enable network
systemctl start network

Configure PBS via /etc/pbs.conf
echo "pbs setup"
systemctl stop pbs
rm -f /etc/pbs.conf
echo "PBS_EXEC=/opt/pbs/default" > /etc/pbs.conf
echo "PBS_HOME=/var/spool/PBS" >> /etc/pbs.conf
echo "PBS_START_SERVER=0" >> /etc/pbs.conf
echo "PBS_START_MOM=1" >> /etc/pbs.conf
echo "PBS_START_SCHED=0" >> /etc/pbs.conf
echo "PBS_START_COMM=0" >> /etc/pbs.conf
echo "PBS_SERVER=PBS_SERVER_HOSTNAME" >> /etc/pbs.conf
echo "PBS_CORE_LIMIT=unlimited" >> /etc/pbs.conf
echo "PBS_SCP=/bin/scp" >> /etc/pbs.conf
echo "PBS_LEAF_ROUTERS=HOSTNAME,HOSTNAME" >> /etc/pbs.conf

pbs.conf must be updated with the cloud node's IP address.
IP=$(ip addr show eth0 | grep "inet\b" | awk '{print $2}' | cut -d/ -f1)
echo "PBS_MOM_NODE_NAME=$IP" >> /etc/pbs.conf

Configure the MoM by updating PBS_HOME/mom_priv/config
echo "mom config setup"
. /etc/pbs.conf
echo "\$clienthost $PBS_SERVER" >> /var/spool/pbs/mom_priv/config
echo "\$clienthost ${PBS_SERVER//.*}" >> /var/spool/pbs/mom_priv/config
echo "\$restrict_user_maxsysid 999" >> /var/spool/pbs/mom_priv/config
```

---

```
Restart pbs
systemctl start pbs
```

## 2.2.5 Adjust PBS\_HOME and PBS\_EXEC if Necessary

If PBS is installed in non-default home and/or execution directories, adjust the values of PBS\_EXEC and/or PBS\_HOME.

## 2.2.6 Additional Configuration

You can use the startup script for other tasks such as configuring filesystems (/etc/fstab), configuring NIS (/etc/yp.conf), and mounting necessary filesystems:

### 2.2.6.1 Creating Local Scratch Space

Create local scratch on a fast local disk and use it as default location to run jobs (use the PBS sandbox feature to place data in job scripts):

```
mkdir /scratch
chmod 1777 /scratch
echo "\$jobdir_root /scratch" >> /var/spool/pbs/mom_priv/config
```

See the *PBS Professional 2020.1 Administrator's Guide*, section 13.13.1.4, “Example of Setting Location for Creation of Staging and Execution Directories”, on page AG-513.

To make it so that jobs with sandbox=PRIVATE have their staging and execution directories created under /scratch, as /scratch/<job-specific\_dir\_name>, put the following line in MoM's configuration file:

```
$jobdir_root /scratch
```

### 2.2.6.2 Mounting a Directory for PBS Data Transfer

Mount /home so that it can be used for PBS data transfer and so that SSH keys stored in the user environment are accessible.

```
echo "PBS_SERVER_IP_ADDR headnode headnode.DOMAINNAME" >> /etc/hosts
...
...
yum install -y nfs-utils
mount -t nfs headnode:/home /home
```

### 2.2.6.3 Configuring the MoM for Local Copy

Use the \$usecp MoM configuration parameter to tell the MoM which local directories are mapped to mounted directories, so that the local copy mechanism can be used.

```
echo "PBS_SERVER_IP_ADDR headnode headnode.DOMAINNAME" >> /etc/hosts
...
...
echo "\$usecp headnode:/home/ /home/" >> /var/spool/pbs/mom_priv/config
```

## 2.2.7 Troubleshooting the Cloud-Init Script

It can be difficult and time consuming to troubleshoot issues with cloud bursting. Some examples of issues that can arise include:

- Network issues
- SSH key issues
- Missing users or groups
- Missing packages
- Mounted file system errors

The recommended mechanism for resolving these issues is through the cloud-init script. The cloud-init script enables automatic configuration of the cloud instance as it boots. An example, cloud-init is provided as part of this documentation and can be used as a starting point.

Firstly, it is recommended to verify that the cloud node is accessible from the PBS Professional server. A suggested approach for testing accessibility and other issues is an iterative process where a single cloud node is burst using the Cloud CLI. Issues are identified and resolved interactively on the burst node command line and a log is maintained of the changes made to the node. The cloud node is unburst using the Cloud CLI, and the logged commands entered at the command-line to resolve the issue are added to the cloud-init script (and parameterized where required). This process is repeated until the cloud node is accessible to the PBS Professional Server. At this point, the cloud hook can be enabled, jobs can be submitted through PBS Professional and cloud bursting hook problems can then be identified and resolved.

### 2.2.7.1 Example of Troubleshooting the cloud-init Script

The steps below provide an example of how a specific issue such as access to SSH keys can be troubleshooted.

1. Create a cloud-init script by copying the example cloud-init script and make any of the necessary modifications as documented.
2. As part of the cloud-init changes, the PBS Server hostname is mapped to its IP address:

```
echo "PBS_SERVER_IP_ADDR headnode headnode.DOMAINNAME" >> /etc/hosts
```

3. Create a bursting scenario using Cloud and upload the cloud-init script as part of this configuration process. Ensure the Add public IP to VMs option is enabled and that a suitable public SSH key is added to the cloud node.

You will need the corresponding private key later in this process.

4. Log in To the PBS Server as root or a user with sudo permissions and set up PBS for cloud bursting including installing the Cloud CLI and the cloud bursting hook.
5. Disable the cloud bursting hook.
6. Use the Cloud CLI to burst a single cloud node:

```
pclm --api-endpoint=http://<CONTROL_HOSTNAME>:9980/pbspro-cloud/ --api-key "<scenario_token>"
 bootstrapper --wait scenario burst '{"mom":[{"deployable_id": "Standard_D4_v2", "count":1}]}'
```

7. Once the node is burst, attempt to SSH into the cloud node using the value of the private\_ip parameter that is returned from the Cloud bursting command.

Result: A “Permission denied” error is encountered.

8. You know that the user’s SSH keys are stored in the user’s home directory under the .ssh directory and the public key has been added to .ssh/authorized\_keys in the user’s home directory so SSH should be working. This indicates that there is a problem with the burst nodes configuration and/or the cloud-init script.

9. Using Putty or a similar SSH client, SSH into the cloud node using the cloud node's public IP address (the value of the parameter `public_ip` address returned from the Cloud bursting command) and your previously generated private SSH key (matching the public key used in the bursting scenario).
10. By checking the contents of the `/etc/hosts` file, it is apparent that the cloud-init script is working because the PBS Server hostname is mapped to its IP address.
11. Check which filesystems have been mounted using the `df` command.  
Result: `/home` is not mounted and is the cause of the SSH failure to the private IP address of the cloud node.
12. Using the `ls` command, you can see that `/home` does exist.
13. To mount the directory, install `nfs-utils` and then mount `/home`.  

```
yum install nfs-utils
mount -t nfs headnode:/home /home
```
14. Unburst the cloud node using the Cloud CLI:  

```
pclm --api-endpoint=http://<CONTROL_HOSTNAME>:9980/pbspro-cloud/ --api-key "<scenario_token>"
bootstrapper --wait scenario unburst <private_ip>
```
15. Log in to Cloud.
16. Edit the bursting scenario.
17. Edit the `init-cloud` script.
18. Copy the two commands to install `nfs-utils` and `mount /home` and paste them into the cloud-init script.
19. Save the cloud-init script.
20. Burst a cloud node and repeat the process.

## 2.3 Configure PBS Professional for Cloud Bursting

Configure the cloud bursting hook, add custom resources for bursting, configure cloud queues and set server cloud limits.

### 2.3.1 Cloud Provider Instance Types

Information about cloud provider instance types.

The instance type (also called shapes, machine types or flavors) determines the hardware of the host computer used for your cloud bursting nodes. Each instance type offers different compute, memory, and storage capabilities. You will need to know what type of instance type you want to burst in the cloud before you can configure PBS Professional. For information about instance types per cloud provider see the following table:

**Table 2-1: Cloud Provider Instance Types**

Provider	URL	Example Instance Types
Azure	Sizes for virtual machines in Azure and High performance compute VM sizes	Standard_DS1_v2, Standard_D2s_v3, Standard_NC6 Standard_H16r, Standard_H16mr (InfiniBand)
AWS	Amazon EC2 Instance Types	t2.medium, r4.large, p3.2xlarge
GCP	Machine Types	n1-standard-8, n1-highmem-2, n1-highcpu-64
Oracle	VM Shapes and GPU Instances	VM.Standard1.1, VM.DenseIO1.16, VM.GPU3.1

**Table 2-1: Cloud Provider Instance Types**

Provider	URL	Example Instance Types
Orange Cloud	Instance Family	s1.medium, s3.large.4, cc3.large.4
HUAWEI Cloud	ECS Types	s2.small.1, s2.medium.4, s2.xlarge.2
OTC	ECS Types	s1.medium, c1.large, m1.xlarge

## 2.3.2 Configure Your Network

A VPN is required from the on-premise network to the cloud network for seamless communication between the two. Test the VPN setup: manually bring up the instance on the cloud and check connectivity between the local and cloud instances.

## 2.3.3 Configure Cloud Bursting Custom Resources

### 2.3.3.1 PBS Professional Custom Resources for Cloud Bursting

Custom resources that must be added to PBS Professional to implement cloud bursting:

#### **cloud\_instance\_type**

Queue-level string

Cloud provider instance type (machine, shape type or flavor) associated to the queue.

#### **cloud\_min\_instances**

Server-level integer.

Minimum number of instances (nodes) to be present in the cloud at any time.

#### **cloud\_max\_instances**

Server-level integer.

Maximum number of instances (nodes) that can be made available in the cloud.

#### **cloud\_max\_jobs\_check\_per\_queue**

Queue-level integer.

The number of queued jobs in the cloud queue that are checked to determine the number of nodes that must be burst based on the instance type requested.

Default is 64. Must be greater than zero. Setting it to zero results in no jobs being considered for cloud bursting in that queue.

#### **cloud\_network**

Host-level string

Used to group a set of nodes with the same network name. Used to request InfiniBand enabled nodes.

#### **cloud\_node\_image**

Host-level string

OS image that is to be used when a cloud node is burst.

**cloud\_node\_instance\_type**

Host-level string

Indicates the default instance type of the cloud node. Is set by the cloud bursting hook when the node is burst.

Node-level string

Indicates the instance type of the cloud node requested at job submission. This overrides the default instance type set at the queue-level. A cloud node is burst with this instance type signature and the job is directed to that cloud node. Is set by the cloud bursting hook when the node is burst.

**cloud\_provisioned\_time**

Host-level integer.

Time at which the cloud node is created.

**cloud\_queue**

Queue-level Boolean

Indicates whether the queue is a cloud queue. When True, the queue is a cloud queue.

**cloud\_scenario**

Node-level, Server-level string.

Indicates the associated scenario type for the queue and the node.

**lic\_signature**

Host-level string.

Contains node hour based information for licensing

**node\_location**

Host-level string.

Used to differentiate local nodes from cloud nodes. It is useful when the site wants the scheduler to try to place jobs on the on-premise nodes first before trying to run them on cloud nodes, while restricting jobs from running on both. Used with placement sets.

### 2.3.3.2 Further Explanation for cloud\_max\_jobs\_check\_per\_queue

The following example further explains the use of cloud\_max\_jobs\_check\_per\_queue.

1. The cloud hook first checks for queued jobs in the cloud queue.
2. It then checks the number of resources it requires to run those jobs.
3. It adds up all the resources required for the queued jobs to run.
4. It calculates the number of nodes required to run the job. Example:

Example 2-1: Suppose there is a cloud queue and the instance type specified for the queue is Standard\_DS2\_V2. The configuration for Standard\_DS1\_v2 is {"ncpus":2, "mem":"8gb"}.

Jobs that are in a queued state in the cloud queue are J1, J2, and J3.

J1 needs 3 CPUs to run.

J2 needs 2 CPUs to run.

J3 needs 5 CPUs to run.

The number of CPUs required to run these jobs is  $3+2+5 = 10$  CPUs.

The number of nodes needed to run all 3 jobs =  $(10 \text{ CPUs} / 2[\text{Standard\_DS2\_V2 number of CPUs}]) = 5$  nodes are needed to burst nodes of type Standard\_DS2\_V2.

---

cloud\_max\_jobs\_check\_per\_queue is set to the default value of 64. If 100 jobs are queued in the cloud queue (J1.....J100), then only the first 64 jobs (J1.....J64) are used to calculate how many nodes need to be burst. You may change the value of cloud\_max\_jobs\_check\_per\_queue to tune cloud bursting.

### 2.3.3.3 Create Cloud Bursting Custom Resources

Add custom resources required to implement cloud bursting.

Creating custom resources must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the PBS Server.
2. Copy and execute the following commands to create the custom resources required for cloud bursting:

```
qmgr -c "create resource cloud_queue type=boolean"
qmgr -c "create resource cloud_instance_type type=string"
qmgr -c "create resource cloud_node_instance_type type=string,flag=h"
qmgr -c "create resource cloud_min_instances type=long"
qmgr -c "create resource cloud_max_instances type=long"
qmgr -c "create resource cloud_provisioned_time type=long,flag=h"
qmgr -c "create resource lic_signature type=string,flag=h"
qmgr -c "create resource cloud_node_image type=string,flag=h"
qmgr -c "create resource cloud_network type=string,flag=h"
qmgr -c "create resource node_location type=string,flag=h"
qmgr -c "create resource cloud_max_jobs_check_per_queue type=long"
```

3. Navigate to PBS\_HOME/sched\_priv.
4. Edit the sched\_config file.
5. Add cloud\_scenario, cloud\_node\_image, and cloud\_node\_instance\_type to the resources line:

```
resources: "ncpus, mem, arch, host, vnode, netwins, aoe, cloud_scenario, cloud_node_image,
cloud_node_instance_type"
```

### 2.3.4 Set Cloud Limits at Server

Set server limits for the minimum and maximum number of cloud nodes and minimum uptime and minimum idle time for a cloud node.

Setting server limits must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the PBS Server.
2. Copy and execute the following commands to set server limits:

```
qmgr -c "set server resources_available.cloud_min_instances = 0"
qmgr -c "set server resources_available.cloud_max_instances = MAX_INSTANCES"
```

Where MAX\_INSTANCES is the maximum number of nodes that can be made available in the cloud and must be expressed as an integer greater than zero.

### 2.3.5 Configure the Cloud Queues

Add and configure the queues necessary for cloud bursting.

Creating and configuring a queue must be done as root or as a user with sudo permissions using the `sudo` command.

The type of node that is burst is defined at the queue-level, unless overridden at job submission time.

To support poly-cloud bursting, the cloud bursting hook has been reformatted allowing scenarios to be added for each cloud provider. A cloud queue must be created for each scenario that is defined in the cloud bursting hook configuration file. Additionally, multiple cloud queues can be created for the same bursting scenario having different instance types allowing different machine types to be burst per cloud provider.

1. Log in to the PBS Server.
2. Copy and execute the following commands to create and configure the cloud queue:

```
qmgr -c "create queue QUEUE_NAME queue_type=execution,enabled=true,started=true"
qmgr -c "set queue QUEUE_NAME resources_available.cloud_queue = True"
```

Where `QUEUE_NAME` is the name of the queue.

3. Optionally, set the maximum number of jobs to check in the queue to determine the number of nodes to burst:

```
qmgr -c "set queue QUEUE_NAME resources_available.cloud_max_jobs_check_per_queue = MAX_JOBS"
```

Where `MAX_JOBS` is the number of queued jobs in the cloud queue that are checked to determine the number of nodes that must be burst based on the instance type requested.

Default is 64. `MAX_JOBS` must be greater than zero. Setting it to zero results in no jobs being considered for cloud bursting in that queue.

4. Assign a bursting scenario to the queue.

```
qmgr -c "set queue QUEUE_NAME resources_available.cloud_scenario = SCENARIO_NAME"
```

Where `SCENARIO_NAME` is the name of the scenario as defined by the cloud bursting hook configuration file. Cloud nodes are burst based on this scenario.

Hook configuration file scenario:

```
"scenario": {
 "azure_scenario_1": {
 "api_key": "API-KEY-HERE",
 "cloud_default_image": "azure_bursting_image1",
 "cloud_max_instances": 10,
 "max_vms_for_infiniband_scaleset" : 100,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
 }
}
```

Associate the scenario with the queue using the command:

```
qmgr -c "set queue QUEUE_NAME resources_available.cloud_scenario = azure_scenario_1"
```

5. Execute the following command to associate an instance type to the queue:

```
qmgr -c "set queue QUEUE_NAME resources_available.cloud_instance_type = INSTANCE_TYPE"
```

Where `INSTANCE_TYPE` is the name of cloud provider instance type. This is the type of machine that will be burst. It must match one of the instance types enabled for the bursting scenario that was just assigned to the queue.

```
qmgr -c "set queue QUEUE_NAME resources_available.cloud_instance_type = Standard_DS2_v2"
```

## 2.3.6 CLI Cloud Bursting Scenario Commands

Command line interface commands that can be used to enable and disable a bursting scenario and get bursting scenario information.

A cloud bursting scenario is created using Cloud and provides information needed for cloud bursting including the cloud provider, region where the node is burst, VPC details, cloud nodes booting script, SSH keys, valid instance types, etc.

Use the Cloud CLI to obtain information about previously created bursting scenarios including its status, enable a bursting scenario so that nodes can be burst, or disable a bursting scenario to restrict nodes from being burst.

Valid status for a bursting scenario are:

### READY

The bursting scenario can be used to burst nodes as long its enabled.

### BUSY

The bursting scenario is in the process of being created.

Information that is required to use these commands:

### HOSTNAME

The IP address or hostname of the machine where Cloud is installed.

### PORT

The port that the Cloud component listens on. Default is 9980.

### API\_KEY

The API Key generated for a cloud bursting scenario.

### SCENARIO\_ID

Unique label that identifies a bursting scenario. Required to enable, disable or get the status of a bursting scenario. Use the Display a List of Bursting Scenarios command to obtain a list of bursting scenarios including the scenario id.

### IDLE\_TIME

Minimum time that a cloud node can be idle before it is unburst. Is expressed as an integer whose units are in seconds. Default is 180 seconds.

### 2.3.6.1 Display a List of Bursting Scenarios

The below command displays a list of bursting scenarios that have been previously created using Cloud.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario list
```

The output of the command is a list of bursting scenarios including the scenario id, the state of the scenario, and whether the scenario is enabled or disabled.

### 2.3.6.2 Enable a Bursting Scenario

The below command enables a bursting scenario so that cloud nodes can be burst using the scenario.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario enable SCENARIO_ID
```

To verify that the bursting scenario is enabled, use the command Display Bursting Scenario Details.

### 2.3.6.3 Disable a Bursting Scenario

The below command disables a bursting scenario. Cloud nodes cannot be burst using a scenario that is

disabled.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario
 disable SCENARIO_ID
```

To verify that the bursting scenario is disabled, use the command Display Bursting Scenario Details.

### 2.3.6.4 Display Bursting Scenario Details

The below command returns information about the bursting scenario:

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario
 show --id SCENARIO_ID
```

The output of the command displays information about the bursting scenario including the scenario id, the state of the scenario, the associated cloud account, and whether the scenario is enabled or disabled.

If you want to display the amount of time before an idle node is unburst, then use the below command (the --raw option must be provided)

```
pclm --raw --api-endpoint=http://HOST:9980/pbspro-cloud/ --api-key KEY bootstrapper scenario show
```

The output of the command is in a JSON format. The idle time is displayed as a key-value pair in the output: {"idle\_before\_unburst": 100}.

### 2.3.6.5 Update the Minimum Time Before an Idle Node is Unburst

The below command updates the bursting scenario setting the minimum time that a cloud node can be idle before it is unburst.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario
 patch --idle-before-unburst IDLE_TIME SCENARIO_ID
```

To verify that the idle before unburst time is updated, use the command Display Bursting Scenario Details with the --raw option.

## 2.3.7 CLI Cloud Bursting Commands

Command line interface commands that can be used to burst and unburst cloud nodes and get status information about a bursting activity.

These commands can be used to test cloud bursting without using the cloud bursting hook. This will ensure that the connectivity from the PBS Server to the cloud infrastructure and the bursting scenarios are working properly. These commands can also be used when a site wants to burst a cloud node so that it remains burst indefinitely.

Cloud nodes burst manually remain up and running until explicitly unburst using the Cloud CLI.

A cloud bursting scenario must be created and a token generated using Cloud before you can burst cloud nodes. Information that is required to use these commands:

#### API\_KEY

The API Key (token) generated for a cloud bursting scenario.

#### COUNT

Indicates the number of nodes to burst.

#### HOSTNAME

The IP address or hostname of the machine where Cloud is installed.

#### MACHINE\_HOSTNAME

Hostname assigned to the cloud node. This information can be obtained by executing the command to display the cloud bursting activity.

**MACHINE\_ID**

A unique label that identifies the cloud node. This information can be obtained by executing the command to display the cloud bursting activity.

**PRIVATE\_IP**

Private IP address assigned to the cloud node. This information can be obtained by executing the command to display the cloud bursting activity.

**MACHINE\_TYPE**

The name of the cloud provider instance type. This is the type of machine that will be burst. It must match one of the instance types enabled for the bursting scenario identified by `API_KEY`.

**PORT**

The port that the Cloud component listens on. Default is 9980.

### 2.3.7.1 Command Options

Options that can be used with the `pclm` command:

**--wait**

Causes the application to wait for the node to be burst/unburst. This option must follow the keyword "bootstrapper".

```
pclm --api-endpoint=http://HOSTNAME::PORT/pbspro-cloud/ --api-key API_KEY bootstrapper --wait
scenario burst \
```

**--raw**

Displays the output of the command in JSON format. This option must follow the keyword "pclm".

```
pclm --raw --api-endpoint=http://HOSTNAME::PORT/pbspro-cloud/ --api-key API_KEY
```

### 2.3.7.2 Command for Bursting Cloud Nodes

The below command bursts a number of cloud nodes based on `COUNT` of type `MACHINE_TYPE` for the bursting scenario identified by `API_KEY`.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper --wait sce-
nario burst '{"mom":[{"deployable_id":"MACHINE_TYPE","count":"COUNT","tags":{"burst-
by":"user"}}]}'
```

The PBS cloud bursting hook always adds a tag called "burst-by" and its value is set to "pbs-cloudhook".

By using the same tag with a different value or a different tag altogether, manually burst nodes can be distinguished from those burst via the bursting hook.

The JSON that describes the type of node to burst and how many to burst can be included directly on the command-line, as shown above, or loaded from a separate file. For example, the following JSON can be copied to a file called `node_to_burst.json`:

```
{ "mom": [{ "deployable_id": "MACHINE_TYPE", "count": "10", "tags": { "burst-by": "user" } }] }
```

The file can then be used as part of the bursting command to load the information.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper --wait sce-
nario burst node_to_burst.json
```

### 2.3.7.3 Command to Display the Status of the Cloud Bursting Activity

The below command displays the status of the cloud bursting activity.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario
status -f tags
```

The status is displayed as a table. Use --raw to display the output of the command in JSON format. The status command displays the machine id, instance type, hostname, private and public IP addresses, the OS image used to create the node, the node's state, and creation time. When the option -f tags is used, any associated tags are displayed as well.

```
(pclm-cli-env)$ pclm $API bootstrapper scenario status -f tags
```

machine_id	instance_type	hostname	private_ip	public_ip	os_image	state	workflow_created_at	tags
71b1f132-3a5d-42fc-9f25-16311e4b0ca2	Standard_B1ls	nodea000003	10.0.0.7	52.168.88.253	pclm-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03	{'u'burst-by': u'user'}
f4c6e65b-6631-4571-8bfe-72d431c82e5	Standard_B1ls	nodea000002	10.0.0.6	52.168.88.231	pclm-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03	{'u'burst-by': u'user'}

Figure 2-2: Command Output

### 2.3.7.4 Cloud Node States

The following is a list of possible virtual machine states. Only a virtual machine that is UP is guaranteed to have an IP addresses and a hostname. A virtual machine that has been fully undeployed will not be present in the output at all.

#### DOWN

Indicates the machine is created in the local database, but not yet in the cloud provider. This status is short-lived and rarely visible.

#### DEPLOYING

Indicates deployment is ongoing.

#### FAILED\_DEPLOYING

Indicates that something has gone wrong and the machine deployment has failed. The virtual machine is automatically unburst in this case.

#### FAILED\_STARTING

Indicates that something has gone wrong and the machine has not started.

#### FAILED\_STOPPING

Indicates that something has gone wrong and the machine has not been stopped.

#### FAILED\_TERMINATING

Indicates that something has gone wrong and the machine has not been terminated.

#### STARTING

Indicates machine is starting.

#### STOPPED

Indicates the machine is stopped.

#### STOPPING

Indicates machine is stopping.

#### TERMINATING

Indicates that machine is being removed.

#### UP

Indicates that the machine deployment has completed and the machine is ready.

### 2.3.7.5 Command for Unbursting Cloud Nodes

The below command unbursts cloud nodes. Use the command to display cloud bursting activity to obtain information about cloud nodes. A cloud node can be unburst using its machine id, private ip address, or hostname.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper --wait scenario unburst
 MACHINE_ID1|PRIVATE_IP1|MACHINE_HOSTNAME1
 MACHINE_ID2|PRIVATE_IP2|MACHINE_HOSTNAME2 [...]
```

Multiple nodes can be unburst in a single call and the parameter used to unburst the nodes can be mixed:

```
unburst MACHINE_ID1 PRIVATE_IP2 MACHINE_HOSTNAME3
```

This information can also be supplied in JSON format on the command-line or in a JSON file:

```
unburst '["MACHINE_ID1", "PRIVATE_IP2", "MACHINE_HOSTNAME3"] '
unburst /tmp/machines_to_unburst.json
```

### 2.3.7.6 Sizing the Network Disk for the Cloud Node Root System

Use the `disk_size_gb` parameter to define the size of the network disk for the root file system in GBs when bursting a cloud node. By default the minimum size is compatible with the image associated with the bursting scenario defined by `API_KEY`.

```
"mom" : [
 {
 "deployable_id": "c3.xlarge",
 "disk_size_gb": 12
 },
 {
 "deployable_id": "d2.xlarge",
 "count": 2,
 "disk_size_gb": 15
 }
]
```

### 2.3.7.7 Preemptible or Spot Instances

Use the `preemptible` parameter to indicate that the cloud node is preemptible (currently implemented for AWS. AWS refers to this as spot instances). This parameter takes a Boolean value. It is preferable that the bursting request either contain only preemptible instances or only non-preemptible instances.

The bursting scenario associated with the `API_KEY` must have spot instances enabled.

```
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper --wait scenario burst "mom":[{"deployable_id": "c3.xlarge","count":"10","preemptible": true}]
```

Possible errors that may occur (returned as JSON, when the `--raw` option is used):

The current spot instance price for Instance Type xx in region yy is higher than the limit configured in the Bursting Scenario zz

The Instance Type xx has not been configured in the Bursting Scenario to be used for spot instances.

### 2.3.7.8 Defining the Image to Use when Bursting

Burst a virtual machine from a specific image using the image parameter. By default, the virtual machine is burst based on the image specified when creating a bursting scenario (defined by the API\_KEY). The value of image depends on the cloud provider. For example, for AWS the name of the AMI is specified:

```
"mom": [{"deployable_id": "t2.medium", "count": "10", "image": "ami-123456"}]
```

For Azure, the resource group into which to place the VM and the name of the image must be specified:

```
"mom": [{"deployable_id": "Standard_DS1_v2", "count": "10", "image": "res-group/imagename"}]
```

### 2.3.7.9 Requesting Infiniband Nodes

When the user wants to run HPC workloads like MPI jobs, the user needs InfiniBand supported nodes deployed on the same InfiniBand network. Among the cloud providers, only Azure currently supports InfiniBand nodes. A restriction for bursting on InfiniBand networks is that jobs cannot run across multiple InfiniBand networks. To prevent this from happening, scale sets can be used. Only virtual machines within the same scale set have InfiniBand connectivity. Use the `infiniband_network` parameter to ensure that all nodes for a bursting request get deployed into the same scaleset.

When bursting InfiniBand nodes, the OS image associated with the bursting scenario defined by API\_KEY must contain everything that is needed to use InfiniBand.

To create a new scaleset, set the value of the `infiniband_network` parameter to “new”:

```
"deployable_id": "Standard_H16mr", "infiniband_network": "new"
```

To use an existing scale set, set the value of the `infiniband_network` parameter to “auto”, which will re-use the existing scale sets as long as all requested nodes fit inside the scale set. If they do not, a new scale set is created for the requested nodes.

```
"deployable_id": "Standard_H16mr", "infiniband_network": "auto"
```

Use the command to display the status of the cloud bursting activity to get information about a node's scaleset. For example:

```
{ ...,
 "scaleset": {"nr": "2", "name": "pclmDEVvhoiAACrxTOHioWSkwg"}, ... }
```

Nodes with the same name value are in the same scaleset.

### 2.3.7.10 Bursting Asynchronously

Sometimes it can take several minutes to burst a cloud node. If you do not want to wait for the bursting command to complete, then eliminate the `--wait` option and provide a unique request identifier. The bursting call will return instantaneously. For example:

```
REQUEST_ID=$(uuidgen)
pclm --api-endpoint=http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY bootstrapper scenario
 burst --request-id $REQUEST_ID '{"mom":[{"deployable_id": "MACHINE_TYPE", "count": "COUNT"}]}'
```

Using the request identifier, poll the list of notifications for the bursting operation to determine its status.

```
pclm --raw --api-endpoint==http://HOSTNAME:PORT/pbspro-cloud/ --api-key API_KEY
notif thread list --request-id $REQUEST_ID --expand
```

Output from the command will look something like this:

```
[
 {
 "title": "Workflow bootstrapper.deploy_deployables",
 "created_at": "2019-10-01T09:02:57.383000+00:00",
 "open": false,
 "related": [...],
 "notifications": [
 ... ,
 {
 "notification_id": "5d93170000b64a0001c4fe00",
 "sender": "executor",
 "message": "Workflow \"deploy_deployables\" execution succeeded",
 "timestamp": "2019-10-01T09:06:08.752000+00:00",
 "content": {
 "workflow": "deploy_deployables",
 "workflow_name": "bootstrapper.deploy_deployables",
 "machine_ids": [
 "a8d1681f-173d-4476-9d52-05e7e1b405d5",
 "535ec0fc-f6f4-4b51-8f9d-abb13984f42d"
],
 "state": "SUCCEEDED",
 "machines": [...],
 ... ,
 },
 ...
 }
],
 ...
 }
]
```

When a final message of success or failure is received, the open parameter is set to “false”. There can be many notifications so be sure to read the last one (the latest timestamp is usually the last one in the list). The state of the notification content can be SUCCEEDED, RUNNING or FAILED.

## 2.3.8 Test Cloud Bursting

### 2.3.8.1 Test Cloud Bursting with the CLI

Test cloud bursting using the Cloud CLI before trying to burst nodes using the cloud bursting hook. This will ensure that the connectivity from the PBS Server to the cloud infrastructure and the bursting scenario are working properly.

Before you begin testing cloud bursting:

1. Ensure that the cloud infrastructure (VPN connectivity, networks, firewalls etc.) is configured.
2. The cloud account and bursting scenario must be configured in Cloud.
3. Generate a token (API Key) for the bursting scenario.

4. The Cloud CLI must be installed.
5. The bursting scenario must be enabled.

### 2.3.8.1.i Burst an Execution Node in the Cloud

Use the Cloud CLI client to burst cloud nodes.

Before you attempt to burst a cloud node, see CLI Cloud Bursting Commands for an explanation on the commands to burst and unburst cloud nodes.

Cloud bursting can be accomplished from the command line by issuing a single command. You can then get the status of the bursting activity and also capture the output in raw JSON format.

Cloud nodes burst manually remain up and running until explicitly unburst using the Cloud CLI.

1. Execute the below command to burst a node in the cloud:

```
pclm --api-endpoint=http://HOSTNAME:9980/pbspro-cloud/ --api-key API_KEY bootstrapper --wait scenario burst '{"mom":[{"deployable_id": "MACHINE_TYPE", "count":COUNT}]}'
```

Where:

- HOSTNAME is the IP address or hostname of the machine where Cloud is installed.
  - MACHINE\_TYPE is the name of the cloud provider instance type. This is the type of machine that will be burst. It must match one of the instance types enabled for the bursting scenario identified by API\_KEY.
  - COUNT indicates the number of nodes to burst.
2. Execute this command to view the status of the cloud bursting activity.

```
pclm --api-endpoint=http://HOSTNAME:9980/pbspro-cloud/ --api-key API_KEY bootstrapper scenario status
```

The status command displays the machine id, instance type, hostname, private and public IP addresses, the OS image used to create the node, the node's state, and workflow creation time.

machine_id	instance_type	hostname	private_ip	public_ip	os_image	state	workflow_created_at
71b1f132-3a5d-42fc-9f25-16311e4b0ca2	Standard_B1ls	nodea000003	10.0.0.7	52.168.88.253	pclm-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03
f4c6e65b-6631-4571-8bfe-72d43c1c82e5	Standard_B1ls	nodea000002	10.0.0.6	52.168.88.231	pclm-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03

Figure 2-3:Command Output

### 2.3.8.1.ii Unburst an Execution Node in the Cloud

Use the Cloud CLI client to unburst cloud nodes.

Before you attempt to unburst a cloud node, see CLI Cloud Bursting Commands for an explanation on the commands to burst and unburst cloud nodes.

Use the Cloud CLI to view the status of the nodes while cloud bursting is in progress. Execute the unbursting command to remove cloud nodes.

1. Execute this command to get the status of the cloud bursting activity.

```
pclm --api-endpoint=http://HOSTNAME:9980/pbspro-cloud/ --api-key API_KEY bootstrapper scenario status
```

Where:

- HOSTNAME is the IP address or hostname of the machine where Cloud is installed.

The status command displays the machine id, instance type, hostname, private and public IP addresses, the OS image used to create the node, the node's state, and workflow creation time.

machine_id	instance_type	hostname	private_ip	public_ip	os_image	state	workflow_created_at
71b1f132-3a5d-42fc-9f25-16311e4b0ca2	Standard_B1ls	nodea000003	10.0.0.7	52.168.88.253	pc1m-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03
f4c6e65b-6631-4571-8bfe-72d43c1c82e5	Standard_B1ls	nodea000002	10.0.0.6	52.168.88.231	pc1m-centos7.4-hpc-cloud-init	UP	2019-09-26 10:50:03

Figure 2-4: Command Output

- Execute this command for unbursting.

```
pc1m --api-endpoint=http://HOSTNAME:9980/pbspro-cloud/ --api-key API_KEY bootstrapper --wait scenario unburst MACHINE_ID|PRIVATE_IP|MACHINE_HOSTNAME
```

A cloud node can be unburst using its machine id, private ip address, or hostname.

Where:

- HOSTNAME is the IP address or hostname of the machine where Cloud is installed.
- MACHINE\_ID is a unique label that identifies the cloud node.
- PRIVATE\_IP is the private IP address assigned to the cloud node.
- MACHINE\_HOSTNAME is the hostname assigned to the cloud node.

### 2.3.8.2 Test Automated Cloud Bursting by Submitting a Job

Test cloud bursting by submitting jobs to cloud queues.

Before you begin testing cloud bursting, a token must be generated for the bursting scenario and the bursting scenario must be enabled.

To troubleshoot issues with the cloud bursting hook, specify that all log events should be captured in the PBS server logs. Make sure to reset this value after testing is complete.

```
qmgr -c "set server log_events=2047"
```

- Submit jobs to the cloud queue.

```
qsub -l select=1:ncpus=4 -q CLOUD_Q JOB_SCRIPT
```

```
qsub -l select=1:ncpus=4 -q CLOUD_Q JOB_SCRIPT
```

Where:

- CLOUD\_Q is the name of the cloud queue.
- JOB\_SCRIPT is the name of the script to be executed.

- Check the status of the jobs:

```
qstat -s
```

- Tail the PBS Professional server logs.

```
tail -f PBS_HOME/server_logs/CURRENT_SERVER_LOG_FILE
```

Where CURRENT\_SERVER\_LOG\_FILE is the most current PBS Server log file.

- Check the current log file to verify that the cloud bursting hook is started. Search for the name of the cloud bursting hook.

```
Server@master;Hook;HOOK_NAME;started
```

Where HOOK\_NAME is the name of the cloud bursting hook.

- Log into Cloud, go to your burst scenario, and you should see the initiation of the workflow that is triggered by the bursting hook. The workflow should automatically start within a couple of minutes.

6. Check the status of the nodes to verify that PBS Professional burst to cloud nodes:

```
pbsnodes -av
```

7. Check the status of the jobs.

Once the node is added, jobs should start running.

```
qstat -s
```

8. You should see that any nodes used only for the test are unburst after the Idle Before Unburst period has elapsed.

## 2.3.9 Configure the Cloud Bursting Hook

Configure the cloud bursting hook that monitors cloud queues, estimates the demand for cloud nodes, and dynamically adjusts the number of nodes by bursting or unbursting as needed.

### 2.3.9.1 Cloud Bursting Periodic Hook

A periodic hook that monitors cloud queues, estimates the demand for cloud nodes, and dynamically adjusts the number of nodes by bursting or unbursting as needed.

The cloud bursting hook defines the types of cloud nodes that can be burst as well as other parameters that control bursting. The scenarios defined in the cloud bursting hook are linked to bursting scenarios created using the Cloud user interface. The linking mechanism is an API key that is generated when a token is added to a bursting scenario via the Cloud user interface. The tokens must be generated before updating the bursting hook.

The cloud bursting hook has been changed so that cloud nodes may be burst across multiple cloud providers. This is useful when your site wants to for instance burst InfiniBand nodes which are currently supported by Azure, but you also want to burst spot instance nodes in AWS. To support this new feature, the cloud bursting hook configuration file now includes a section called scenario. A scenario must be added to the cloud bursting hook configuration file for each cloud provider.

The DNS setup that was required for previous versions of the cloud bursting hook is no longer required. Cloud nodes are accessed through their IP address, therefore the DNS information in the hook configuration file has been removed.

Lastly, the cloud bursting hook now obtains the instance types from Cloud, therefore the instance types are no longer managed through the hook's configuration file.

The cloud bursting configuration file contains the following parameters:

#### **pclm\_server**

Endpoint for accessing Cloud in the format `http://hostname:port` or `http://ipaddress:port`. Default port is 9980.

#### **cloud\_min\_instances**

Minimum number of instances to be present in the cloud at any time. Does not apply during startup; cloud nodes are not immediately burst on startup. This is the minimum number that are maintained after they are initially burst on demand. This value is overridden by the same value set at the server-level.

#### **resources**

Resources to be considered for calculating the number of nodes to burst. Resources that are currently supported are: "ncpus", "mem", "ngpus".

#### **cloud\_driver**

Indicates the driver class implementation in the hook.

Currently, the only value supported is "PclmDriver". DO NOT change this value.

**scenario**

Container for bursting scenarios. You can have scenarios for each cloud provider or multiple scenarios for a cloud provider or both.

**Restriction:** Each bursting scenario should have its own `api_key`.

**scenario\_1...n****api\_key**

Token generated for a bursting scenario via the Cloud user interface. The value should be unique for each bursting scenario.

**cloud\_default\_image**

OS image that is to be used by default when a cloud node is burst. This is overridden when the OS image is provided at job submission via the `qsubcommand`.

**cloud\_max\_instances**

Maximum number of instances that can be made available in the cloud for this scenario. Is expressed by an integer and must be greater than 0. This value must be specified otherwise the cloud bursting hook is rejected.

**max\_vms\_for\_infiniband\_scaleset (Optional)**

Defines the number of nodes on an single InfiniBand switch. Supported by Azure only. This limit is set by Azure and the current default is 100. Customers may negotiate with Azure to increase this limit. In this case, the value of this parameter should be updated.

**max\_nodes\_per\_burst**

Maximum number of nodes allowed to burst in a single hook cycle. Maximum number of cloud node licenses to renew per hook cycle.

**cloud\_node\_wait\_timeout**

Maximum time to wait for freshly burst node to become usable. Is expressed as an integer whose units are in seconds. Default is 180 seconds. You can set this to a higher value, but a lower value defaults to 180 seconds.

**preemptable (Optional)**

This flag is set to True if the scenario is supporting preemptible (spot) instances. Default value is False for a scenario. If flag is not specified, the default value is used. Useful when using cloud spot instances for running short re-runnable jobs that could be preempted.

### 2.3.9.2 Default Cloud Bursting Hook Configuration File

```
{
 "pclm_server": "pclm_server:port_number",
 "cloud_min_instances": 1,
 "resources":["ncpus", "mem", "ngpus"],
 "cloud_driver": "PclmDriver",
 "scenario": {
 "azure_scenario_1": {
 "api_key": "API-KEY-HERE",
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 10,
 "max_vms_for_infiniband_scaleset" : 100,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
 },
 "aws_scenario_1": {
 "api_key": "API-KEY-HERE",
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 20,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
 },
 "aws_scenario_2": {
 "api_key": "API KEY HERE",
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 50,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
 }
 }
}
```

### 2.3.9.3 Cloud Hook Considerations

Each bursting scenario should have its own unique `api_key`. The below example where the same `api_key` is used for two bursting scenarios where the only difference is the maximum amount of cloud nodes that can be burst is not supported and may result in unexpected bursting behavior.

```
"aws_scenario_1": {
 "api_key": "uqldIqmgS6el4PMm0FDdZw3duy7cNAZACPGgpnxxl0jbMViIgx3_YXC"
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 20,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
},
"aws_scenario_2": {
 "api_key": "uqldIqmgS6el4PMm0FDdZw3duy7cNAZACPGgpnxxl0jbMViIgx3_YXC"
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 50,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180
}
```

### 2.3.9.4 Configure the Cloud Bursting Hook

Configure the cloud bursting hook per your site's requirements and then re-import it. Configuring the hook must be done as root or as a user with sudo permissions using the `sudo` command.

The scenarios defined in the cloud bursting hook are linked to bursting scenarios created using the Cloud user interface. The linking mechanism is an API key that is generated when a token is added to a bursting scenario via the Cloud user interface. The tokens must be generated before updating the bursting hook.

Export the cloud bursting hook configuration file, update its parameters per your site's requirements, and then re-import the hook.

1. Export the cloud bursting hook configuration to a file:

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

Where `FILENAME` is the name of the file where the hook configuration is written.

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```

2. Edit the file.
3. Set `pclm_server` to the endpoint for accessing Cloud in the format `http://HOSTNAME:9980`. Where `HOSTNAME` is the IP address or hostname of the machine where Cloud is installed.
4. Set the value of `cloud_min_instances` to the minimum number of instances to be present in the cloud at any time.

This value must be specified otherwise the cloud bursting hook is rejected.

5. Set `resources` to a comma separated list of resources that are to be considered for calculating the number of nodes to burst.

```
[“ncpus”, “mem”, “ngpus”] OR [“ncpus”, “mem”]
```

6. For each scenario to be added to the scenario container:

- a. Set the value of `api_key` to the token generated for the bursting scenario.
- b. Set the value of `cloud_default_image` to OS image that should be used for bursting. This OS image is used if the image is not requested as part of the job submission request.
- c. Set the value of `cloud_max_instances` to the maximum number of instances that can be made available in the cloud.  
Must be expressed an integer greater than zero. This value must be specified otherwise the cloud bursting hook is rejected.
- d. Optionally, set the value of `max_vms_for_infiniband_scale` to define the maximum number of nodes allowed on a single InfiniBand switch.  
This value should match the value of Maximum number of VMs inside a ScaleSet as specified in the Azure bursting scenario. If you are not using InfiniBand, then you can eliminate this parameter.
- e. Set the value of `max_nodes_per_burst` to the maximum number of nodes allowed to burst in a single hook cycle.
- f. Set the value of `cloud_node_wait_timeout` to the maximum time to wait for freshly burst node to become usable.  
Must be expressed as an integer whose units are in seconds. Default is 180 seconds. You can set this to a higher value, but a lower value defaults to 180 seconds.
- g. Set preemptible to:
  - True when the bursting scenario supports preemptible (spot) instances and cloud jobs may be preempted.
  - False when jobs that are run in the cloud should not be preemptible.
 Default value is False for a scenario. If flag is not specified, the default value is used.

7. Re-import the hook with the updated configuration values:

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

Where FILENAME is the name of the file containing the hook configuration.

```
qmgr -c "import hook cloud_hook application/x-config default config.json"
```

8. Optionally, set the cloud bursting hook frequency.

The default frequency for the cloud bursting hook to execute is every 2 minutes.

```
qmgr -c "set hook cloud_hook freq=FREQUENCY"
```

Where FREQUENCY is the frequency for the hook to execute. Must be expressed as an integer whose units are in seconds.

9. Set the cloud bursting hook alarm:

You must set the hook alarm; otherwise, the hook will time out after the default value of 600 seconds. Tune the alarm value to something greater than the default. Consider the following factors:

- Time required to burst nodes on the cloud
- Time required to unburst nodes on the cloud
- Number of cloud queues

**Recommendation:** Set the alarm to at least 20 minutes (1200 seconds).

```
qmgr -c "set hook cloud_hook alarm=ALARM_TIME"
```

Where ALARM\_TIME must be expressed as an integer whose units are in seconds.

10. Enable the cloud bursting hook.

The cloud bursting server periodic hook is disabled by default.

```
qmgr -c "set hook cloud_hook enabled=True"
```

## 2.4 Manage Cloud Bursting

Enable and disable cloud bursting and edit cloud bursting scenarios to reconfigure cloud bursting such as adding instance types, updating the cloud node boot script, and managing SSH keys.

### 2.4.1 View Cloud Account Details

View the information that was entered to create a cloud account.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.
4. Select a cloud account by clicking on its name.

The information that was entered to create the cloud account is displayed.

5. Click Close.

### 2.4.2 View the Cloud Burst Nodes

View the cloud nodes that have been burst for a bursting scenario. Information that is displayed about cloud burst nodes:

**Machine Name**

Hostname of the node.

**IP Address**

IP address assigned to the node.

**Instance Type**

Cloud provider instance type (machine type, shape or flavor) of cloud node.

**Image**

OS image used to burst the node.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Bursting.
4. Select a bursting scenario by clicking on its name.

Any cloud nodes that have been burst are displayed under the Machines category.

Machines			
Machine Name	IP Address	Instance type	Image
mcr10-12-3-223	10.12.3.223	t2.micro	ami-b40efcce

Figure 2-5: Burst Cloud Nodes

### 2.4.3 Enable Cloud Bursting

Enable cloud bursting so that cloud nodes can be burst.

By default, a bursting scenario is disabled after creation. To begin cloud bursting, a bursting scenario must first be enabled.

1. Log in to Cloud.
2. Click Cloud.
3. Click the Bursting tab on the left-hand side of the web page.
4. Enable a bursting scenario by clicking located to the far right of the scenario name.
5. Click Enable.
6. Repeat the last two steps to enable additional bursting scenarios.

### 2.4.4 Disable Cloud Bursting

Disable cloud bursting by disabling a bursting scenario, draining the cloud queues associated with the bursting scenario, and waiting until all cloud nodes unburst.

Disabling a bursting scenario locks the bursting scenario from accepting any new bursting requests, but does not unburst any cloud nodes. This allows jobs that have been submitted to a cloud queue associated with the bursting scenario to run and complete. Once all jobs are complete, the node is unburst when it has remained idle for a specific amount of time.

**Tip:** The timeframe that a cloud node can be idle before it is unburst is configurable through the cloud bursting hook or using the Cloud CLI to update the bursting scenario.

Repeat the below instructions for all bursting scenarios to disable bursting entirely. For instance, when upgrading PBS Professional, performing PBS maintenance, or reconfiguring PBS execution hosts.

1. Log in to Cloud.
2. Click Cloud.
3. Click the Bursting tab on the left-hand side of the web page.
4. Disable a bursting scenario by clicking located to the far right of the scenario name.
5. Click Disable.
6. Allow the cloud queues associated to the bursting scenario to drain by allowing time for the jobs that are waiting in the queues to run and complete.

If a running job is taking a long time to complete, it can be deleted using the PBS `qdel` command.

7. Verify that all cloud nodes are unburst:
  - a. Click on the name of a cloud bursting scenario.
  - b. View the information displayed under the Machines heading.

When the following message is displayed, all cloud nodes are unburst.

No machines are available

### 2.4.5 Edit a Bursting Scenario

Edit a bursting scenario to add quotas and alerts, enable instance types, add or remove SSH keys, and make changes to the cloud node startup script.

---

Before you can edit a bursting scenario, any cloud nodes that are currently burst for that scenario must be drained and unburst. For more information see [Disable Cloud Bursting](#).

### 2.4.5.1 Add Quotas and Alerts

Add optional resource quotas and alerts to control cloud bursting.

To control cloud bursting, quotas can be added to define bursting limits for the following resources:

- the number of CPUs
- the amount of RBudget
- the amount of nodes
- the amount of node hours

Once the limit is reached, additional nodes are not burst. Alerts can also be defined so that an email is sent by a SMTP server when a limit is reached.

The SMTP server is configured during installation of Cloud by your site's system administrator.

1. Log in to Cloud.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click the name of the bursting scenario.
5. Click Add Quota.
6. For Resource type, choose a resource from the menu.
7. Click Add Quota.
8. For Limit, provide a limit for the resource.

When the limit is reached for the resource, the deployment of further cloud burst nodes is blocked.

9. To add an alert, click Add.
10. Provide an alert value.

When the alert value is reached, an email is sent if an SMTP server is configured.

11. Repeat steps 5 through 10 to add quotas and alerts for other resources types.

### 2.4.5.2 Add a Token

Create a token and associated API key for a bursting scenario. The API key is used in the cloud bursting hook.

You can create a token right after creating a bursting scenario or you can create a token at a later date.

1. Log in to Cloud.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click the name of the bursting scenario.
5. Click Add token located at the bottom of the web page.
6. For Name, enter a name for the token.
7. For Expiration date, specify the expiration date in MM/DD/YYYY format.
8. Click Add Token.

---

An API key is generated and displayed.

9. Copy and save this API key.

The API key is only displayed once. It is pasted in the configuration file used to configure the cloud bursting hook.

10. Click Close.

Once the token is created, there is additional configuration that needs to occur for PBS Professional; see [section 2.3, “Configure PBS Professional for Cloud Bursting”](#), on page 21.

## 2.4.6 Enable Instance Types

Enable instance types for a bursting scenario so that nodes having that hardware configuration can be burst.

1. Log in to Cloud.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click the name of the bursting scenario.
5. Click Edit Instances.
6. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

`TYPE is not enabled`

Where TYPE is the instance type used when attempting to burst the node.

7. Click Save.

The instance types that have been enabled for the bursting scenario are displayed.

## 2.4.7 Edit General Bursting Scenario Details

Modify bursting scenario details such as scenario name, description, domain name, OS image, and VPC details.

1. Log in to Cloud.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click the name of the bursting scenario.

- Click the edit pen.

Information	
State	<span style="color: green;">■</span> READY
Name	aws-ohio
Description	AWS nodes running in Ohio
Cloud provider	aws
Cloud account name	aws_cloud_bursting
Region	us-east-2
AMI ID	ami-0b714e61c388be45b
Subnet ID	subnet-3cc00a47
Idle before unburst	200
Domain name	altair
Hostname prefix	node
Security group ID	sg-0e64ccbce7bb50b2e
Add public IP to VMs	<input checked="" type="checkbox"/>

Tags: tag1:value1 tag2:value2

Figure 2-6:Edit Scenario Details

- Change any of the editable data.
- Enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as key:value. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

Tags: tag1:value1 x

Figure 2-7:Key-Value Tag

- Repeat the previous step to add more tags.

Tags: tag1:value1 x tag2:value2 x

Figure 2-8:Additional Tags

- Click Save.

### 2.4.7.1 Edit SSH Keys

Add an SSH to a bursting scenario to give users access to associated cloud nodes. Remove SSH keys for a bursting scenario to restrict access to the associated cloud nodes.

- Log in to Cloud.
- Click Cloud.
- Under Infrastructure, click Bursting.
- Click the name of the bursting scenario.
- Click the edit pen.

6. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Click Add.  
An editable box is displayed.
  - b. Place the cursor in the editable box.
  - c. Paste the public SSH key into the editable box.  
Public key files are usually stored in `/.ssh` in the user's home directory.
  - d. Repeat steps 6.a through 6.c to add additional public SSH keys.
7. Remove public SSH keys so that users do not have access to the burst nodes:  
Click the "x" located next to the SSH key box.
8. Click Save.

### 2.4.7.2 Edit the Cloud Node Startup Script

Update the cloud node startup script to configure the node after booting.

1. Log in to Cloud.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click the name of the bursting scenario.
5. Click the edit pen .
6. Modify the script.
7. Click Save.

## 2.4.8 Manage Manually Burst Cloud Nodes

Burst, unburst and view information about cloud nodes that have been created manually.

Manually burst cloud nodes are those that have either been created using the Cloud CLI or through the Cloud user interface and have not been created via the PBS cloud bursting hook.

### 2.4.8.1 Burst a Cloud Node Manually

Burst nodes manually (without the intervention of the PBS cloud bursting hook) for testing purposes or when your site wants to keep nodes burst for an indeterminate amount of time.

A cloud bursting scenario must be created before you can burst cloud nodes.

Cloud nodes can be burst manually (without using the PBS cloud bursting hook) to test the bursting scenario, to ensure that the connectivity from the PBS Server to the cloud infrastructure is working properly, or so that the cloud node remains burst indefinitely.

Cloud nodes burst manually remain up and running until explicitly unburst.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Bursting.
4. Select a bursting scenario by clicking on its name.

- Under Machines (manually burst), click Manual bursting.

A list of instance types that have been enabled for the bursting scenario is displayed.

- Click the “+” to choose an instance type to burst.

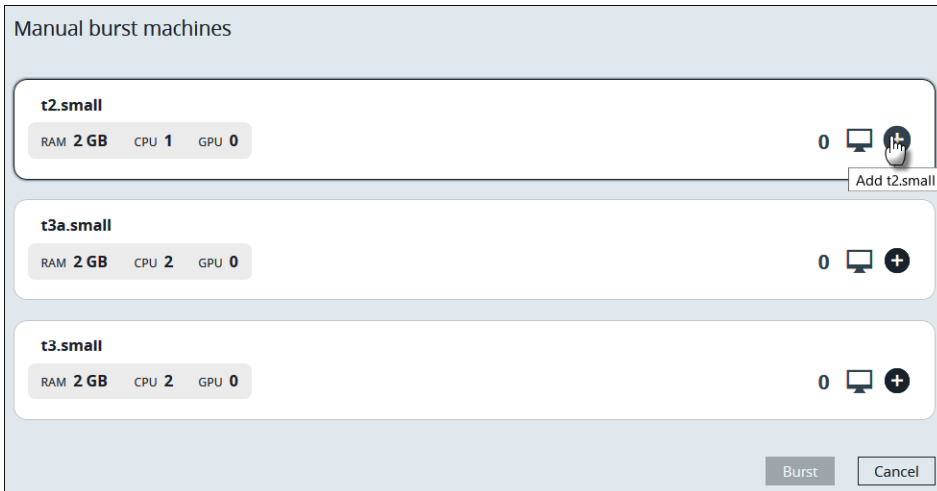

Figure 2-9: Choose Instance Type

- Enter the number of machines to burst.

Figure 2-10: Number of Machines to Burst

- Optionally, override the default OS image by entering a different OS image. An OS image is the template used to create the virtual machine.

Figure 2-11: Override the OS Image

- Optionally, click again to burst the same instance type with a different OS image.

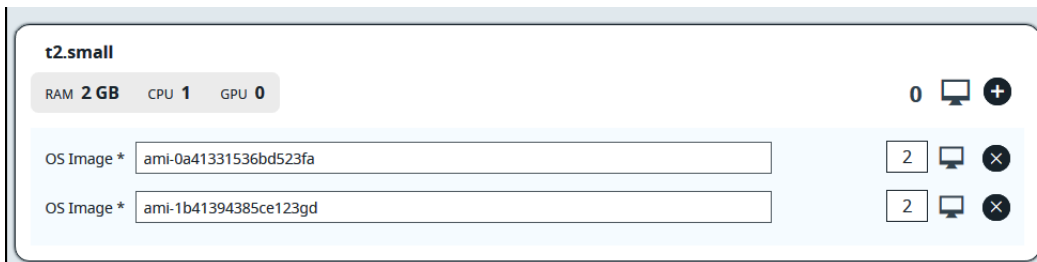

Figure 2-12: Choose a Different OS Image

10. Repeat steps 6 through 9 to burst any other instance types.
  11. Click Burst xx machines.  
Where xx indicates the number of virtual machines that will be burst.
  12. Click Burst xx machines to confirm the action.
  13. Click the bell icon to view messages in the Notification Center about the progress of the bursting activity.
- Once bursting is complete, a list of virtual machine that have been burst is displayed.

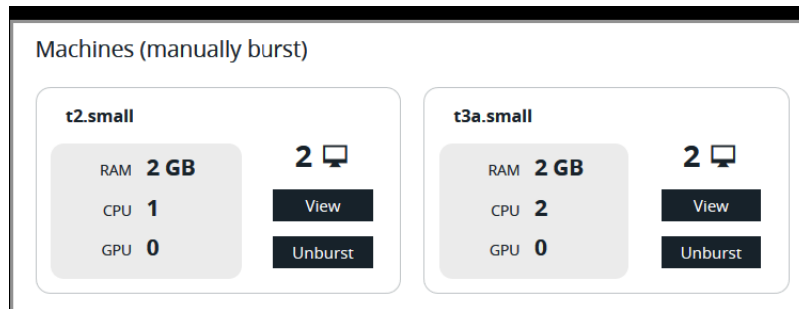

Figure 2-13: Burst Machines

### 2.4.8.2 View Information About a Manually Burst Cloud Node

Display information about a manually burst node such as machine name, IP address, associated OS image and price.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Bursting.
4. Select a bursting scenario by clicking on its name.
5. Under Machines (manually burst), click View to display information about the machines that have been burst for a particular instance type.

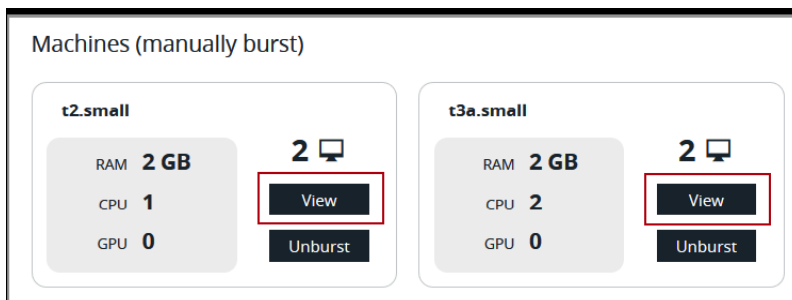

Figure 2-14: View Machine Information

Use the search boxes located above the columns to filter a long list of machines.

Manual unburst machines for t2.small

Machine Name ^	IP Address	Image	Price
<input type="text"/>	<input type="text"/>	<input type="text"/>	
node10-0-1-161	13.233.113.67	ami-0a41331536bd523fa	-
node10-0-1-36	35.154.21.122	ami-0a41331536bd523fa	-

Cancel

Figure 2-15:Machine Information

### 2.4.8.3 Unburst a Manually Burst Cloud Node

Unburst nodes that were created manually when they are no longer needed.

Before unbursting, drain the cloud node of any running jobs, otherwise jobs that are running when the node is unburst will fail.

Cloud nodes burst manually remain up and running until explicitly unburst.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Bursting.
4. Select a bursting scenario by clicking on its name.
5. Under Machines (manually burst), choose on of the following options:
  - To display all machines that have been manually burst, click Manual unbursting located to the right of the web page.
  - To display a list of machines that have been burst for a particular instance type, click Unburst.

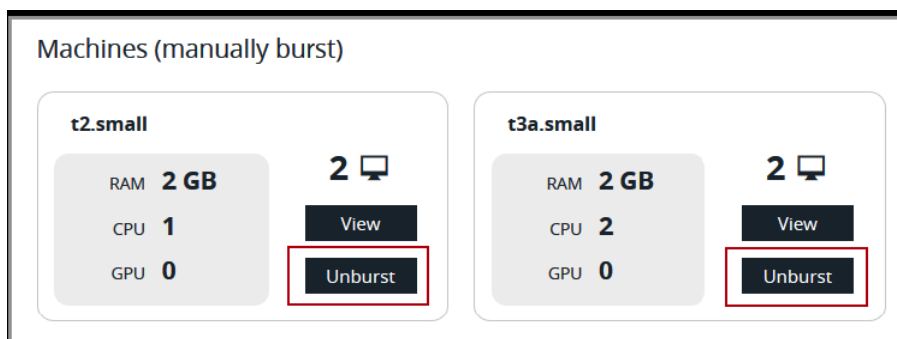

Figure 2-16:Unburst Machines for a Particular Instance Type

- Choose machines to unburst by enabling the check box to the right of the machine.

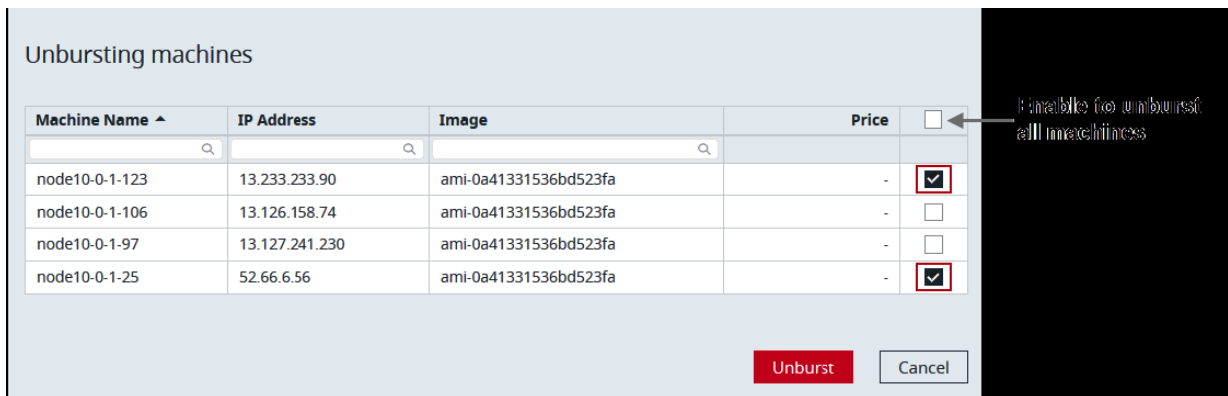

Figure 2-17: Choose Machines to Unburst

- Click Unburst.
- Click Unburst machines to confirm the action.
- Click the bell icon to view messages in the Notification Center about the progress of the unbursting activity.

## 2.5 Troubleshoot Cloud Bursting

View log messages to troubleshoot cloud bursting.

View the log messages that are written to PBS\_HOME/server\_logs on the PBS Server to troubleshoot cloud bursting. Additionally, you can SSH to the virtual machine that was burst and check PBS\_HOME/mom\_logs to debug issues with node creation or issues with starting the MoM on that virtual machine.

A third option for troubleshooting cloud bursting is to use Cloud to view the logs through a Kibana user interface.

### 2.5.1 PBS MoM s Stopped or Down

When cloud bursting is implemented and all PBS MoM's are stopped or down, error messages similar to the below may be seen in the PBS Server logs:

```
Server@server;Hook;Server@server;CLBR: Error: /opt/pbs/bin/pbsnodes: Server has no node list
Server@server;Hook;Server@server;CLBR: Error: Failed to get nodes info
```

Resolve the issue by starting at least one MoM.

## 2.6 Manage Cloud and On-Premise Jobs

Solutions to handle various job distribution needs.

Your site may want to run certain types of jobs on-premises or in the cloud. PBS Professional provides various methods to collect and distribute jobs. For more information see Routing Jobs in the PBS Professional Administrator's Guide.

Here are some solutions to handle various job distribution needs.

## 2.6.1 Associate Nodes with Queues

In general, start by associating nodes with queues, so that a job in a specific queue is sent to the desired nodes. Associate each on-premise vnode with the appropriate local queue. Set the queue attribute on the vnode to the name of the local queue:

```
qmgr -c "active <list of on-premise nodes>"
qmgr -c "set node queue=<name of local queue>"
```

For more information see *Creating Queues and Associating Vnodes With One Queue* in the *PBS Professional Administrator's Guide*.

## 2.6.2 Use Hooks or Routing Queues to Send Jobs to the Appropriate Queue

To send jobs to the appropriate queue on submission, use hooks or routing queues. For more information see the *PBS Professional Hooks Guide* and *Routing Queues* in the *PBS Professional Administrator's Guide*.

## 2.6.3 Job Distribution Examples and Solutions

Examples for routing jobs to the cloud.

### 2.6.3.1 Burst when On-premise Nodes are Not Available

You want to run as many jobs as possible on on-premise nodes, and only burst to the cloud when no more on-premise nodes are available.

Solution: Create two execution queues, one for local jobs and one for cloud jobs. Set up local peering so that the local queue pulls from the cloud queue whenever local nodes are available.

### 2.6.3.2 Send Small Jobs to the Cloud

You have big machines for on-premise nodes and want to reserve those big machines for big jobs. You want to send smaller jobs to the cloud.

Solution 1:

- Create three queues: a routing queue, a local queue, and a cloud queue.
- Use the routing queue to collect jobs on submission.
- Set resource gating on the local queue to filter out smaller jobs.
- Allow smaller jobs into the cloud queue.

Solution 2:

- Create two queues: a local queue, and a cloud queue.
- Use a queuejob hook to route jobs into the appropriate queue.

### 2.6.3.3 Send Specific Jobs Only to the Cloud

You want to send specific jobs to the cloud because:

- an application needed by some jobs runs well in the cloud.
- a resource that is available in the cloud is not available locally.
- a department has exhausted its share of local resources, and wants to send its jobs to the cloud.

Solution :

- Create two queues: a local queue, and a cloud queue.
- Use a queuejob hook to route jobs into the appropriate queue.

### 2.6.3.4 Charge Departments for Resources Used

You have multiple departments and each department should be charged for the resources it uses.

Solution :

- Create a cloud queue for each department.
- Set separate limits on each cloud queue.

## 2.7 Run Cloud Jobs On-Premise Before Bursting

Use placement sets to run jobs on-premise first and burst cloud nodes when local nodes are not available.

Assign a bursting scenario to an on-premise vnode so that cloud jobs are run on-premise when there is capacity. Cloud nodes are only burst when on-premise nodes are not available.

For more information see Placement Sets in the PBS Professional Administrator's Guide.

1. Create a custom resource to indicate that a node is on-premise.

```
qmgr -c "create resource node_location type=string,flag=h"
```

2. For each on-premise vnode, set the resources\_available.node\_location resource to "local" to indicate that it is on-premise.

```
qmgr -c "active node VNODE_NAME"
```

```
qmgr -c "set node VNODE_NAME resources_available.node_location=local"
```

Where VNODE\_NAME is the name of the local vnode.

3. For any on-premise vnodes where you want to run cloud jobs, associate a bursting scenario or a list of bursting scenarios to the vnode:

- To associate a list of bursting scenarios to a vnode:

```
qmgr -c "set node VNODE_NAME resources_available.cloud_scenario= SCENARIO_1,
SCENARIO_2,...,SCENARIO_n"
```

- To associate a single bursting scenario to a vnode:

```
qmgr -c "set node VNODE_NAME resources_available.cloud_scenario= SCENARIO_1"
```

Where SCENARIO\_1,..., SCENARIO\_n are scenario names that have been added to the cloud bursting hook configuration file.

```
qmgr -c "set node VNODE_NAME resources_available.cloud_scenario=
azure_scenario_1,aws_scenario_1,aws_scenario_2"
```

4. Create a dummy vnode with a high resources\_available.ncpus value and unset resources\_available.node\_location.
5. Mark the dummy node as offline so that jobs cannot run on it.

```
pbsnodes -C "COMMENT" -o HOSTNAME
```

Where COMMENT is a string explaining that this is a dummy node for cloud bursting and HOSTNAME is the host-name of the vnode.

6. Enable placement sets:

```
qmgr -c "set server node_group_enable=true"
qmgr -c "set server node_group_key=node_location"
```

7. Allow creation of placement sets from unset resources:

```
qmgr -c "set sched only_explicit_psets=false"
```

8. Optionally, prevent any single job from running on both local and cloud vnodes:

```
qmgr -c "set sched do_not_span_psets=true"
```

9. Navigate to PBS\_HOME/sched\_priv.

10. Edit the sched\_config file.

11. Add cloud\_scenario and node\_location to the resources line:

```
"... , cloud_scenario, node_location"
```

12. For each local (non-cloud) queue set its node\_location to "local":

```
qmgr -c "set queue QUEUE_NAME resources_default.node_location=local"
```

Where QUEUE\_NAME is the name of the local queue.

13. For each cloud queue, verify that the value of resources\_default.node\_location is unset.

14. Restart or HUP the scheduler:

```
kill -HUP <scheduler PID>
```

## 2.7.1 Override Instance Type or Image at Job Submission

Override the default instance type or OS image used to burst the cloud node at job submission.

The OS image that is to be used when a cloud node is burst can be specified at job submission via the `qsub` command. If this information is not provided at job submission, then the OS image defaults to the value of the `cloud_default_image` parameter in the cloud bursting hook configuration file.

The job submitter can use only the instance types that have been allowed by the administrator. If the job submitter tries to use a non-allowed instance type, the job does not run.

Additionally, the instance type that is burst can be specified at job submission via the `qsub` command (e.g. `Standard_DS3_v2`). Instance types are defined by the cloud provider. The name of the instance type must exactly match the cloud provider's. If this information is not provided at job submission, then the instance type defaults to the instance type defined for the cloud queue.

1. Override the cloud image at job submission via the `qsub` command:

```
qsub -l select=1:ncpus=4 -q QUEUE_NAME -v CLOUD_IMAGE=IMAGE JOB_SCRIPT
```

Where:

- QUEUE\_NAME is the name of the cloud queue.
- JOB\_SCRIPT is the name of the script to be executed.
- IMAGE is the name of the OS image to be used when the node is burst.

2. Override the cloud instance at job submission via the `qsub` command:

```
qsub -l select=1:ncpus=4 -q QUEUE_NAME -v CLOUD_INSTANCE=INSTANCE_TYPE JOB_SCRIPT
```

Where:

- `QUEUE_NAME` is the name of the cloud queue.
- `JOB_SCRIPT` is the name of the script to be executed.
- `INSTANCE_TYPE` is the name of cloud provider instance type. This is the type of machine that will be burst.

3. You can also override both the OS image and the instance type as part of the `qsub` command:

```
qsub -l select=1:ncpus=4 -q QUEUE_NAME -v CLOUD_IMAGE=IMAGE,CLOUD_
```

## 2.7.2 Request InfiniBand Nodes

Request InfiniBand nodes to run HPC workloads like MPI jobs.

You will need to create an InfiniBand enabled OS image before you can submit a job to an InfiniBand cloud node.

When the user wants to run HPC workloads like MPI jobs, the user needs InfiniBand supported nodes deployed on the same InfiniBand network. Among the cloud providers, only Azure currently supports InfiniBand nodes. Azure limits the number of nodes on a single Infiniband network (current default limit is 100), however your site may set up multiple Infiniband networks. A restriction for bursting on Infiniband networks is that PBS jobs cannot run across multiple Infiniband networks. To prevent this from happening, placement sets can be used.

At job submission, the user can request InfiniBand nodes by requesting an InfiniBand supported instance type, an InfiniBand enabled OS image, and an InfiniBand network.

Upon bursting an InfiniBand node, the name of the network is obtained from the cloud provider. The custom resource `cloud_network` on the Infiniband node is updated with this value. All nodes on the same Infiniband network have this custom resource set to the same value. This value is then used to restrict jobs to run within the same network, using placement sets.

1. Enable placement sets:

```
qmgr -c "set server node_group_key=cloud_network"
qmgr -c "set server node_group_enable=true"
```

2. Prevent any single job from running across multiple Infiniband networks:

```
qmgr -c "set sched do_not_span_psets=true"
```

3. Request Infiniband nodes by overriding the cloud image and the cloud instance and requesting an Infiniband network via the `qsub` command:

```
qsub -l select=1:ncpus=4 -q QUEUE_NAME -v
 CLOUD_IMAGE=IMAGE,CLOUD_INSTANCE=INSTANCE_TYPE,CLOUD_NETWORK=IB JOB_SCRIPT
```

Where:

- `QUEUE_NAME` is the name of the cloud queue.
- `INSTANCE_TYPE` is the name of cloud provider instance type (machine types, shapes or flavors) and should be an instance type that supports Infiniband.
- `IMAGE` is the name of the Infiniband enabled OS image to be used when the node is burst.
- `CLOUD_NETWORK=IB` requests an Infiniband network
- `JOB_SCRIPT` is the name of the script to be executed.

## 2.8 Modify the Bursting Hook

Add, remove or change a scenario in the cloud bursting hook configuration file.

---

Modifying any of the following parameters in the cloud bursting hook configuration file does not require any special processing. The cloud bursting hook will use the updated values in the next hook cycle:

- `cloud_min_instances`
- `resources`

## 2.8.1 Change a Scenario in the Cloud Bursting Hook

Make modifications to an existing scenario in the cloud bursting hook.

Configuring the hook must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the PBS Server.
2. Export the cloud bursting hook configuration to a file:

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

Where FILENAME is the name of the file where the hook configuration is written.

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```

3. Edit the file.
4. Make any necessary adjustments to the scenario.
5. Save the file.
6. Re-import the hook with the updated configuration values:

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

Where FILENAME is the name of the file containing the hook configuration.

## 2.8.2 Add a New Scenario to the Cloud Bursting Hook

Modify the cloud bursting hook configuration file by adding a new scenario.

Each scenario requires its own queue, and each queue can have only one scenario, otherwise bursting and unbursting will not be coordinated.

Configuring the hook must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the PBS Server.
2. Export the cloud bursting hook configuration to a file:

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

Where FILENAME is the name of the file where the hook configuration is written.

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```

3. Edit the file.

4. Add a scenario by adding the following information to the scenario container. Note that scenarios are specific to a cloud provider.
  - a. Set the value of `api_key` to the token generated for the bursting scenario.
  - b. Set the value of `cloud_default_image` to OS image that should be used for bursting. This OS image is used if the image is not requested as part of the job submission request.
  - c. Set the value of `cloud_max_instances` to the maximum number of instances that can be made available in the cloud.  
Is expressed as an integer whose units are in seconds. This value must be specified otherwise the cloud bursting hook is rejected.
  - d. Optionally, set the value of `max_vms_for_infiniband_scale` to define the maximum number of nodes allowed on a single InfiniBand switch.  
This value should match the value of Maximum number of VMs inside a ScaleSet as specified in the Azure bursting scenario. If you are not using InfiniBand, then you can eliminate this parameter.  
Supported by Azure only.
  - e. Set the value of `max_nodes_per_burst` to the maximum number of nodes allowed to burst in a single hook cycle.
  - f. Set the value of `cloud_node_wait_timeout` to the maximum time to wait for freshly burst node to become usable.  
Must be expressed as an integer whose units are in seconds. Default is 180 seconds. You can set this to a higher value, but a lower value defaults to 180 seconds.
  - g. Set preemptible to:
    - True when the bursting scenario supports preemptible (spot) instances and cloud jobs may be preempted.
    - False when jobs that are run in the cloud should not be preemptible.
 Default value is False for a scenario. If flag is not specified, the default value is used.
5. Save the file.
6. Re-import the hook with the updated configuration values:
 

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

 Where FILENAME is the name of the file containing the hook configuration.

Now you must add and configure a new cloud queue for the scenario: see [section 2.3.5, “Configure the Cloud Queues”](#), on page 24.

## 2.8.3 Delete a Scenario from the Cloud Bursting Hook

Remove a scenario that is no longer needed from the cloud bursting hook configuration file. Before deleting a scenario from the cloud bursting hook configuration file, disable cloud bursting.

Configuring the hook must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the PBS Server.
2. Export the cloud bursting hook configuration to a file:
 

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

 Where FILENAME is the name of the file where the hook configuration is written.
 

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```
3. Edit the file.

4. Remove the scenario from the scenario container.
5. Save the file.
6. Re-import the hook with the updated configuration values:  

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

Where FILENAME is the name of the file containing the hook configuration.
7. Enable all cloud queues.  

```
qmgr -c "set queue QUEUE_NAME enabled=true"
```

Where QUEUE\_NAME is the name of the cloud queue.

## 2.8.4 Change the Cloud Server

Update the hook configuration file when the location of the Cloud component changes.

Before making any changes to the endpoint for accessing the Cloud component, disable cloud bursting.

1. Log in to the PBS Server.
2. Export the cloud bursting hook configuration to a file:  

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

Where FILENAME is the name of the file where the hook configuration is written.  

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```
3. Edit the file.
4. Set pclm\_server to the endpoint for accessing Cloud in the format http://HOSTNAME:PORT.  
Where HOSTNAME is the IP address or hostname of the machine where Cloud is installed and PORT is the Cloud port (Defaults to 9980).
5. Re-import the hook with the updated configuration values:  

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

Where FILENAME is the name of the file containing the hook configuration.
6. Enable all cloud queues.  

```
qmgr -c "set queue QUEUE_NAME enabled=true"
```

Where QUEUE\_NAME is the name of the cloud queue.

## 2.9 Start and Stop Cloud After a Manual Installation

### 2.9.1 Start Cloud

Start the Cloud service after a manual installation.

Starting Cloud must be done as root or as a user with sudo permissions using the sudo command.

---

When your server hosting the Cloud component reboots, containers are restarted automatically. If you need to manually start Cloud containers, please follow the below instructions.

1. Log in to the machine where Cloud is installed.
2. Enter the following command to start Cloud:

```
pkcr start
```

## 2.9.2 Stop Cloud

Stop the Cloud service after a manual installation.

Stopping Cloud must be done as root or as a user with sudo permissions using the sudo command.

1. Log in to the machine where Cloud is installed.
2. Enter the following command to stop Cloud:

```
pkcr stop
```

## 2.9.3 Restart Cloud

Retart the Cloud service after a manual installation.

Retarting Cloud must be done as root or as a user with sudo permissions using the sudo command.

When your server hosting the Cloud component reboots, containers are restarted automatically. If you need to manually restart Cloud containers, please follow below instructions.

1. Log in to the machine where Cloud is installed.
2. Enter the following command to restart Cloud:

```
pkcr restart
```

## 2.9.4 Determine the Status of the Cloud Service

Determine whether the Cloud service is up or down.

1. Log in to the machine where Cloud is installed.
2. Enter the following command to display the status of the Cloud service:

```
pkcr status
```

# Using Cloud Provider Services

## 3.1 Windows Bursting on AWS and Azure

Bursting of Windows virtual machines is supported on AWS and Azure. Windows cloud bursting is similar to cloud bursting on Linux platforms. Three special requirements are necessary to burst Windows cloud nodes.

### 3.1.1 OS Image Name

When creating the OS image, the name of the image must contain the term “windows” (case insensitive). For example, on AWS, the AMI Name should look something like this:

Windows\_Server-2012-R2\_RTM-English-64Bit- Base-2019.11.13

On Azure, the Image Name should look something like Windows Server 2012 R2 Datacenter.

### 3.1.2 Inbound Security Rule for RDP

Secondly, an inbound rule to open the port 3389 must be added to the AWS security group or the Azure network security group that is associated with the cloud provider virtual network. This allows a connection to be made to the Windows VM via RDP so that the PBS MoM can be installed.

For more information see [AWS: Authorizing Inbound Traffic for Your Windows Instances](#) and [Azure: Cannot connect remotely to a VM because RDP port is not enabled in NSG](#).

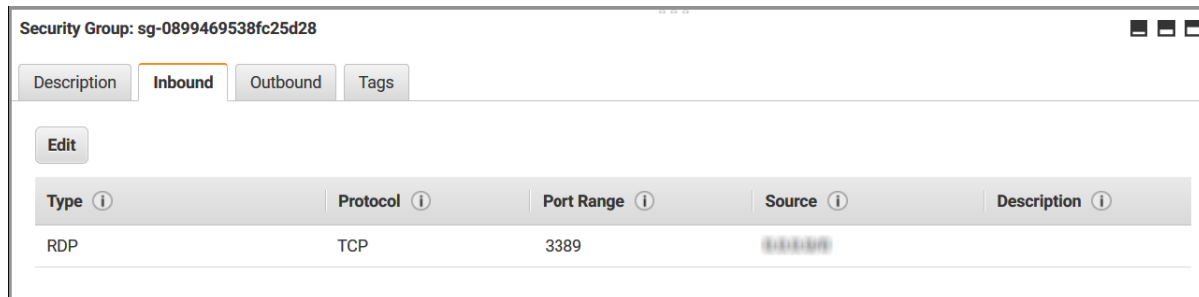

Figure 3-1:AWS Inbound Security Rule for RDP

+ Add  Default rules						
Priority	Name	Port	Protocol	Source	Destination	Action
430	RDP	3389	Any		Any	Allow ...

Figure 3-2:Azure Inbound Security Rule for RDP

### 3.1.3 Startup Script

The cloud node startup script must use a PowerShell script. For more information see PowerShell Scripting. The below PowerShell script example generates a file in C:\Windows\Temp:

```
<powershell>
$file = $env:SystemRoot + "\Temp\" + (Get-Date).ToString("MM-dd-yy-hh-mm")
New-Item $file -ItemType file
</powershell>
```

### 3.1.4 See Also

- ["Configuring Amazon Web Service Cloud Bursting" on page 60](#)
- ["Configuring Microsoft Azure Cloud Bursting" on page 73](#)

## 3.2 Configuring Amazon Web Service Cloud Bursting

You create and activate an AWS account, create the AWS components required for cloud bursting, and then create a Cloud cloud bursting scenario.

For more information see [How do I create and activate a new Amazon Web Services account?](#)

You'll need the AWS user account in order to create a cloud account in Cloud.

You create an AWS user account and give this account administrative permissions. Once this task is complete, you should have downloaded a CSV file containing the following:

- Access key ID
- Secret access key

This information is necessary to create a cloud account in Cloud.

### 3.2.1 Creating an Amazon Web Service User Account

1. Sign up for an AWS account.

You can find AWS documentation at [Creating an IAM User in Your AWS Account](#).

2. Log in to the AWS console.
3. Using the search box located under AWS services, enter IAM.
4. Click the IAM search result.

The Identity and Access Management dashboard is opened.

5. In the navigation pane on the left-hand side of the web page, click Users.
6. Click Add user.

This user will have administrative rights to any machines hosted in the cloud.

7. Enter the following information to add a user:
  - a. For User name, enter a name for the user.  
The name can be anything meaningful to your organization, e.g., pc\_clouduser.
  - b. For Access type, enable Programmatic access.  
The user requires this type of access because Cloud needs to make API calls or use the AWS CLI. An access key ID and a secret access key are generated for the user.
8. Click Next:Permissions.
9. Optional: Click Add user to group. This button may already be selected.
10. Click Create group.
11. Enter the following information to create a group, add the user to the group, and choose a permission policy for the group.
  - a. For Group name, enter a group name.  
The name can be anything meaningful to your organization, e.g., pc\_cloudgroup.
  - b. For Policy type, enable AdministratorAccess.  
This policy provides full access to AWS services and resources.
12. Click Create group.  
You are returned to the Add user page and the new group is enabled indicating that the user is added to the new group.
13. Click Next: Tags.
14. Click Next: Review.
15. Click Create user.
16. Click Download.csv.
17. Download and save this file in a secure location.  
This file contains an access key ID and a secret access key and is used later to add a cloud account to Cloud.
18. Click Close.  
The new user account is displayed.

### 3.2.2 Add an Amazon Web Service Cloud Account

Add an existing AWS user account Cloud so that you can create a cloud bursting scenario or an appliance.

You must already created an AWS user account, given it administrative permissions and downloaded a CSV file containing an access key ID and a secret access key. The information in the CSV file is necessary to create a cloud account in Cloud. If you do not have this information see Create an Amazon Web Service User Account.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.
4. Click the “AWS” button.

5. Enter the following to add a cloud account:
  - a. For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., `aws_cloudaccount`.
  - b. For Access Key ID, copy and paste the value of Access key ID from the downloaded CSV file.
  - c. For Secret Access Key, copy and paste the Secret access key value from the downloaded CSV file.
  - d. Click Create account.

### 3.2.3 Multi-Availability Zone Management on AWS

Configure the bursting scenario so that cloud nodes can be burst in several Availability Zones.

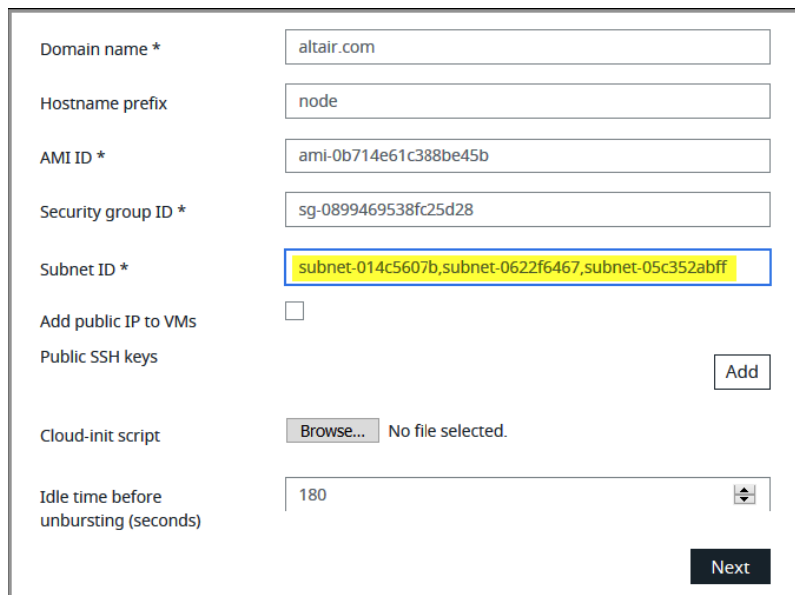

Refer to the following AWS documentation if you are not familiar with AWS regions, Availability Zones, VPCs or subnets:

- Regions, Availability Zones, and Local Zones
- VPCs and Subnets

Bursting cloud nodes in multiple Availability Zones allows an HPC complex to distribute the load across a region and take advantage of AWS Spot Instances. Several prerequisites must be met before configuring the bursting scenario:

- An AWS virtual private cloud (VPC) must be created.
- A subnet for each Availability Zone must be created and each subnet must belong to the same VPC.

Once these prerequisites are met, then it is as simple as providing a comma-separated list of subnets when the bursting scenario is created.

The screenshot shows a configuration form with the following fields and values:

- Domain name \*: `altair.com`
- Hostname prefix: `node`
- AMI ID \*: `ami-0b714e61c388be45b`
- Security group ID \*: `sg-0899469538fc25d28`
- Subnet ID \*: `subnet-014c5607b,subnet-0622f6467,subnet-05c352abff` (highlighted with a yellow box)
- Add public IP to VMs: ☐
- Public SSH keys:
- Cloud-init script:  No file selected.
- Idle time before unbursting (seconds): `180`
- 

Figure 3-3:List of Subnets

Cloud attempts to burst cloud nodes in the first subnet in the list. If there is no availability in that subnet, then it will attempt to burst cloud nodes in the next subnet in the list and will continue until a subnet is found where the cloud nodes can be burst or until all subnets are exhausted (i.e. bursting fails). The cloud bursting hook attempts to burst all requested cloud nodes in a single subnet. Cloud nodes are not burst across subnets. This same process is followed each bursting cycle until there is availability for the cloud nodes.

Example 3-1: 10 cloud nodes are requested for bursting.

- a. The cloud bursting hook attempts to burst all 10 nodes in subnet-014c5607b.
- b. If there is no availability in subnet-014c5607b, the hook attempts to burst all 10 cloud nodes in subnet-0622f6467.
- c. If there is no availability in subnet-0622f6467, the hook attempts to burst all 10 cloud nodes in subnet-05c352abff.
- d. If there is no availability in subnet-05c352abff, then cloud bursting fails.

### 3.2.4 Create a Virtual Private Cloud Network

Create a Virtual Private Cloud (VPC) in AWS so that you can later create a virtual machine for cloud bursting.log in to your AWS Management Console and choose a region based on the geographical location of your users. All cloud resources that are created are placed in this region. For more information see Regions and Availability Zones. The menu for selecting a region is located at the upper right-hand corner of the AWS Console menu bar.

Figure 3-4:AWS Region

AWS documentation can be found at [Getting Started with IPv4 for Amazon VPC](#) and [Working with VPCs and Subnets](#).

To configure the bursting scenario so that cloud nodes can be burst in several Availability Zones, create a subnet for each Availability Zone that you want to burst in. For more information see [Multi-Availability Zone Management on AWS](#).

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter VPC.
4. Click the VPC search result. The VPC dashboard is opened.
5. In the menu located on the left-hand side of the web page, click Your VPCs. Create a virtual private cloud.
6. Click Create VPC.
7. Enter the following to create a VPC:
  - a. For Name, enter any name for the VPC.  
The name can be anything meaningful to your organization, e.g., bursting\_vpc.
  - b. For IPv4 CIDR block, provide an address range in CIDR notation.
  - c. For IPv6 CIDR block, enable No IPv6 CIDR Block.
  - d. For Tenancy, choose Default.
8. Click Yes, Create.
9. Create subnets for the VPC:
10. In the menu located on the left-hand side of the web page, click Subnets.

11. Click Create Subnet.
  - a. For Name tag, enter a name for the subnet.  
The name can be anything meaningful to your organization, e.g., `bursting_subnet`.
  - b. For VPC, choose the VPC that was previously created (e.g. `bursting_vpc`).
  - c. For Availability Zone, choose one of the following options:
    - Choose a unique availability zone for each subnet.
    - Choose No Preference to let Amazon choose an Availability Zone for you.
  - d. For IPv4 CIDR block, provide an address range in CIDR notation.
12. Click Create.
13. Click Close.

### 3.2.5 Create an Internet Gateway

Create an internet gateway and attach it to the bursting VPC. AWS documentation can be found at [Internet Gateways](#). An internet gateway must be created so that you can later SSH into the virtual machine that is used for cloud bursting.

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter VPC.
4. Click the VPC search result. The VPC dashboard is opened.
5. In the menu located on the left-hand side of the web page, click Internet Gateways.
6. Click Create internet gateway.
7. Enter the following to create an internet gateway:
  - For Name tag, enter a name for the internet gateway.  
The name can be anything meaningful to your organization, e.g., `bursting_gateway`
8. Click Create.
9. Click Close.
10. Select the internet gateway that was just created by enabling the check box next to the name of the gateway.
11. You may need to deselect any other internet gateways that are displayed in the list. Amazon creates default resources for your selected region so a default internet gateway may already exist.
12. Click Actions > Attach to VPC.
13. Select the VPC that was created previously (e.g. `bursting_vpc`).
14. Click Attach.

### 3.2.6 Update the VPC Route Table

Add a rule to the VPC route table that allows all internet access and associate the route table to the bursting subnet.

AWS documentation can be found at Route Tables.

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter VPC.
4. Click the VPC search result. The VPC dashboard is opened.
5. In the menu located on the left-hand side of the web page, click Route Tables. A list of route tables is displayed.
6. Select the route table attached to your VPC (e.g. bursting\_vpc) by enabling the check box next to the name of the route table.

The VPC column in the route table list specifies the VPC to which the route table is attached.

7. Click the Routes tab at the bottom of the web page.
8. Click Edit routes.

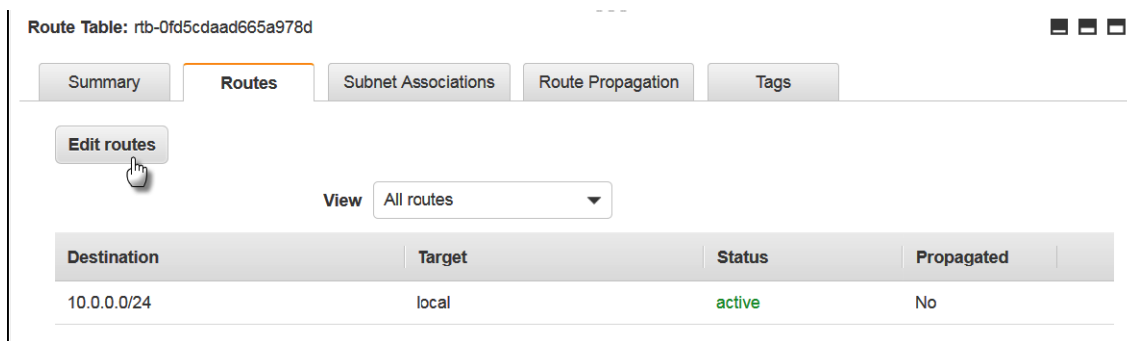

Figure 3-5: Add a Route

9. Click Add route.
10. Add a rule that allows all traffic access to the internet gateway:
  - a. Enter the following to add a rule:
    - For Destination enter 0.0.0.0/0.
    - For Target, select Internet Gateway and then the internet gateway that was created previously (e.g. bursting\_gateway).
11. Click Save routes.
12. Click Close.
13. Associated the route table to the bursting subnet:
  - a. Click the Subnet Associations tab.
  - b. Click Edit subnet associations.
  - c. Select the subnet created for cloud bursting from the list.
14. Click Save.

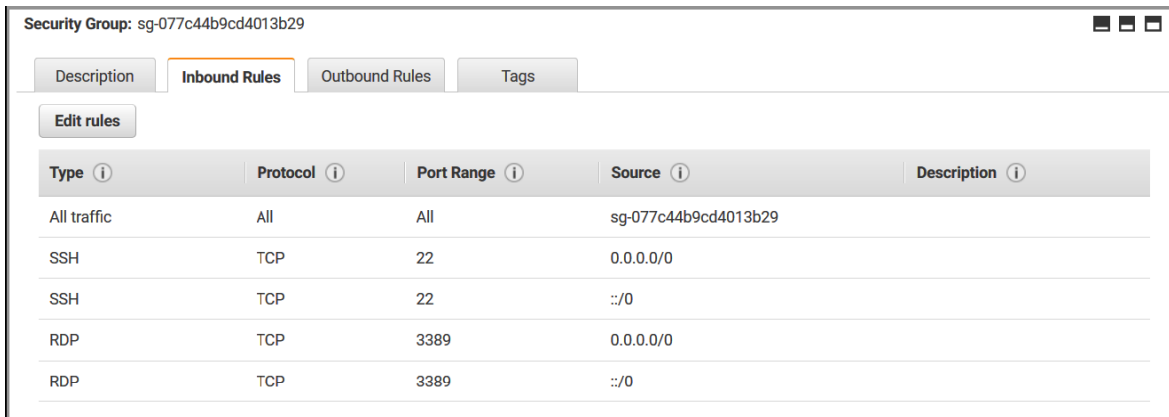

### 3.2.7 Add Inbound Rules to the VPC Security Group

Add inbound rules to the VPC security group so that a connection can be established with an AWS VM using SSH or RDP.

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter VPC.
4. Click the VPC search result. The VPC dashboard is opened.
5. In the menu located on the left-hand side of the web page, under Security click Security Groups.
6. Select the security group associated to the VPC created for cloud bursting by enabling the check box next to its name.

A default VPC security group is created when the VPC is created.

7. Click the Inbound Rules tab at the bottom of the web page.
8. Click Edit rules.
9. Click Add Rule.
10. Add security rules based on your site's requirements.
  - On Linux platforms, add an inbound rule to allow SSH traffic on port 22.
  - On Windows platforms, add an inbound rule to allow RDP traffic on port 3389.

Type	Protocol	Port Range	Source	Description
All traffic	All	All	sg-077c44b9cd4013b29	
SSH	TCP	22	0.0.0.0/0	
SSH	TCP	22	::/0	
RDP	TCP	3389	0.0.0.0/0	
RDP	TCP	3389	::/0	

Figure 3-6: Security Rules

**Warning:** 0.0.0.0/0 enables all IPv4 addresses to access your instance. ::/0 enables all IPv6 address to access your instance. This is acceptable for a short time in a test environment, but it's unsafe for production environments. In production, authorize only a specific IP address or range of addresses to access your instance.

11. Click Save rules.

### 3.2.8 Create a Virtual Machine

Create a virtual machine in AWS Elastic Compute Cloud (EC2).

---

AWS documentation can be found at [Launch a Linux Virtual Machine](#) and [Launching a Virtual Machine with Amazon EC2](#).

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter EC2.
4. Click the EC2 search result. The EC2 dashboard is opened.
5. In the menu located on the left-hand side of the web page, click Instances.
6. Click Launch Instance.
7. In the menu located on the left-hand side of the web page, click AWS Marketplace.
8. Using the search box:
  - On Linux platforms, enter CentOS 7 or RHEL and press ENTER.
  - On Windows platforms, enter Windows and press ENTER.
9. Locate the appropriate Amazon Machine Image (AMI) and click Select.

On Linux platforms, cloud bursting has been tested on CentOS 7.2 - 7.6.

On Windows platforms, cloud bursting has been tested on Windows 10 and Windows Server 2012.
10. Click Continue.
11. Select an Instance Type appropriate for your site's workload based on:
  - the number of cores
  - the amount of memory
  - storage
  - network performance

Consider the nature of the applications that you plan to deploy on the instance, the number of users that you expect to use the applications, and also how you expect the load to scale in the future. Remember to also factor in the CPU and memory resources that are necessary for the operating system.
12. Click Next: Configure Instance Details.
13. Enter the following to configure instance details:
  - a. For Number of instances, specify 1.
  - b. For Network, choose the VPC that you previously created (e.g. bursting\_vpc). The bursting subnet is automatically populated.
  - c. For Auto-assign Public IP, select Enable.
14. Click Next: Add Storage.
15. Specify the storage options as per your site's requirements. We recommend enabling Delete on Termination to delete EBS volumes when the virtual machine is terminated.
16. Click Next: Add Tags.
17. Optional: You can add tags in key-value pairs for the VM per your site's requirements.
18. Click Next: Configure Security Group.

19. Enter the following to assign a security group to the VM:
  - a. For Assign a security group, enable Select an existing security group.
  - b. Select the security group that was automatically created for the cloud bursting VPC by enabling the check box next to its name.
20. Click Review and Launch.
21. Review the VM information of the VM and click Launch.
22. Create a new public/private key pair for the VM by entering the following:
  - a. Select Create a new key pair.
  - b. Provide a name for the key pair.
  - c. Click Download Key Pair.
  - d. Download and save this file in a secure location.
23. Click Launch Instances.
24. At the bottom of the web page, click View Instances.

All virtual machines that have been created are displayed.

Your virtual machine is ready when the Instance State is equal to “running” and Status Checks are complete. The virtual machine can be accessed using its IPv4 Public IP.

Name	Instance ID	Instance Type	Availability Zone	Instance State	Status Checks	Alarm Status	Public DNS (IPv4)	IPv4 Public IP	IPv6 IPs
	i-03c94330e8c14e619	t2.micro	us-east-1f	running	2/2 checks	None		18.206.92.183	-

Figure 3-7: Bursting Virtual Machine

## 3.2.9 Install the PBS MoM on the VM

Install the PBS Professional MoM on the virtual machine and configure the VM per your site’s environment.

### 3.2.9.1 Install the PBS MoM on the Linux VM

Install the PBS Professional MoM on the Linux virtual machine and configure the VM per your site’s environment.

On Linux platforms, the username for logging into the virtual machine is dependent on the Amazon Machine Image (AMI) that you used to create the virtual machine. For example, the username for a CentOS AMI is “centos”. For information about usernames and instructions for connecting and copying files to the Linux virtual machine see Connecting to Your Linux Instance Using SSH.

You will need the .pem file downloaded while creating the VM to establish a connection.

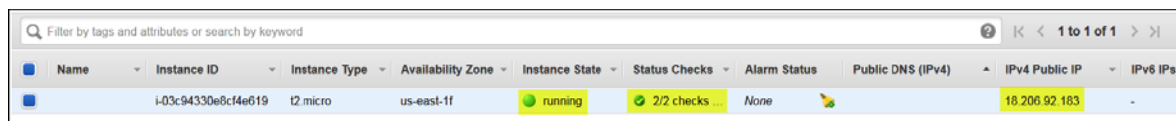

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

The PBS Professional installer package will need to be copied to the virtual machine. Use SCP to copy the tarball file from the PBS Server to the virtual machine. For more information, see [Transferring Files to Linux Instances from Linux Using SCP](#).

1. Log in to your site's PBS Professional Server.
2. SSH into the virtual machine as the user "centos" using the .pem file and the IPv4 Public IP assigned to the VM:

```
ssh -i /path/my-key-pair.pem centos@IPv4PublicIP
```

where /path/my-key-pair.pem is the path to the .pem file downloaded while creating the virtual machine and IPv4PublicIP is the public IP address of the virtual machine.

Name	Instance ID	Instance Type	Availability Zone	Instance State	Status Checks	Alarm Status	Public DNS (IPv4)	IPv4 Public IP	IPv6 IPs
	i-03c94330e8c4e619	t2.micro	us-east-1f	running	2/2 checks	None		18.206.92.183	

Figure 3-8: Bursting Virtual Machine

3. Enter the command:  

```
sudo -i
```
4. Copy the PBS Professional installation package to the VM.
5. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS Professional MOM.
6. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
7. Install cloud-init.
8. Connect the VM to your PBS Professional server and submit a job to ensure it is working as expected.

### 3.2.9.2 Installing the PBS MoM on the Windows VM

Install the PBS Professional MoM on the Windows virtual machine and configure the VM per your site's environment.

Use an RDP client to access the virtual machine. A connection can be established to the Windows virtual machine through the AWS EC2 console. See [Connect to Your Windows Instance](#) for more information.

You will need the .pem file downloaded while creating the VM to establish a connection.

The PBS Professional installer package will need to be copied to the virtual machine. Use RDP to map a local drive to gain access to the installer package. For more information, see [Transfer Files to Windows Instances](#).

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter EC2.
4. Click the EC2 search result.
5. In the menu located on the left-hand side of the web page, click Instances.
6. Select the Windows virtual machine created for cloud bursting by enabling the check box next to its name.
7. At the top, click Connect.
8. Click Get Password.
9. Browse to the .pem file downloaded while creating the VM.
10. Open the .pem file.
11. Click Decrypt Password.

12. Hover over the decrypted password.  
A copy to clipboard icon is displayed.
13. Click the copy to clipboard icon.
14. Click Download Remote Desktop File.
15. Open the file.
16. Click Connect.
17. For Password, paste the password copied to the clipboard.
18. Click OK.
19. Click Yes to connect even if there are certificate errors.  
A connection is established with the Windows virtual machine.
20. Copy the PBS Professional installation package to the VM.
21. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS Professional MOM.
22. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
23. Connect the VM to your PBS Professional server and submit a job to ensure it is working as expected.

### 3.2.10 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

You must have already create a virtual machine, installed the PBS Professional MoM on the VM and configured the VM per your site's environment.

AWS documentation can be found at [Create an AMI from an Amazon EC2 Instance](#).

1. Log in to the AWS console.
2. Click  located in the upper left-hand corner of the web page.
3. Using the search box located under AWS services, enter EC2.
4. Click the EC2 search result. The EC2 dashboard is opened.
5. In the menu located on the left-hand side of the web page, click Instances.
6. Select the virtual machine created for cloud bursting by enabling the check box next to its name.
7. At the top, click Actions > Instance State > Stop.
8. Click Yes, Stop.

It may take some time for the virtual machine to be stopped.

Do not proceed until the Instance State is "Stopped".

9. Click Actions > Image > Create Image.
10. For Image name, enter a name for the image.

The name can be anything meaningful to your organization, e.g., bursting\_image.

On Windows platforms, the name of the image should contain the string "windows" (case-insensitive). For example, Windows\_Server-2012-R2\_\_RTM-English-64Bit-Base-2019.11.13.

11. Click Create Image.

12. Click the View pending image ami-xxxxxxxxxx link. The image is complete when its Status is “available”.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.2.11 Create an AWS Cloud Bursting Scenario

Create an AWS bursting scenario so that PBS Professional execution nodes can be burst in the cloud.

Open a browser window and log in to your AWS Management Console. Open a second browser window and log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. On Windows platforms, the startup script must be a PowerShell script. For more information see PowerShell Scripting. On Linux platforms, use a cloud-init script.

For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a registered AWS account from the list.
  - d. Select a region from the list that matches the region selected in AWS.

Figure 3-9:AWS Region

6. Click Next.
7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.  
If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the AWS browser window.
10. Click  located in the upper left-hand corner of the web page.
11. Using the search box located under AWS services, enter EC2.
12. Click the EC2 search result. The EC2 dashboard is opened.
13. In the menu located on the left-hand side of the web page, click AMIs.
14. Select the Amazon Machine Image (AMI) created for cloud bursting by enabling the check box next to its name.
15. In the Details tab located at the bottom of the web page, hover over the AMI ID.  
A copy to clipboard icon is displayed.

16. Click the copy to clipboard icon.
17. Navigate to the Cloud browser window.
18. For the AMI ID, paste the AMI ID copied from AWS.
19. Navigate to the AWS browser window.
20. In the menu located on the left-hand side of the web page, click Security Groups under NETWORK & SECURITY.
21. Select the Security Group associated with the VPC and the VM by enabling the check box next to its Group ID.
22. In the Description tab located at the bottom of the web page, hover over the Group ID. A copy to clipboard icon is displayed.
23. Click.
24. Navigate to the Cloud browser window.
25. For the Security group ID, paste the Group ID copied from AWS.
26. Navigate to the AWS browser window.
27. Click  located in the upper left-hand corner of the web page.
28. Using the search box located under AWS services, enter VPC.
29. Click the VPC search result. The VPC dashboard is opened.
30. In the menu located on the left-hand side of the web page, click Subnets.
31. Select the subnet for the bursting VPC by enabling the check box next to its name.
32. In the Description tab located at the bottom of the web page, hover over the Subnet ID. A copy to clipboard icon is displayed.
33. Click the copy to clipboard icon.
34. Navigate to the Cloud browser window.
35. For the Subnet ID, paste the Subnet ID copied from AWS.

To configure the bursting scenario so that cloud nodes can be burst in several Availability Zones, providing a comma-separated list of subnet IDs.
36. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.

It is recommended to leave this disabled.
37. For Cloud-init script, click Browse, browse for the startup script file and select it. This script will run after a cloud node is burst.
38. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Log in to the PBS Professional Server.
  - b. Copy the public SSH key for the user.

Public key files are usually stored in `/.ssh` in the user's home directory.
  - c. Navigate to the Cloud browser window.
  - d. Click Add to add the public key.
  - e. For Public SSH keys, paste the public SSH key.
  - f. Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.
39. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.

It is expressed as an integer whose units are in seconds.

40. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as key:value. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

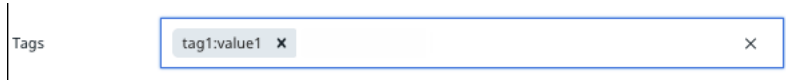

Figure 3-10:Key-Value Tag

41. Repeat the previous step to add more tags.

Figure 3-11:Additional Tags

42. Click Next.
43. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

44. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.3 Configuring Microsoft Azure Cloud Bursting

Create the necessary components in Microsoft Azure that are required for cloud bursting and then create a Cloud cloud bursting scenario.

Before you can begin creating the Azure components necessary for cloud bursting, you must purchase an Azure subscription and have created a tenant. For more information about subscriptions see What is an Azure subscription. For more information about tenants How to get an Azure Active Directory tenant. As a final step, add users to the Active Directory.

### 3.3.1 Register the Cloud Application with Azure

Register Cloud with Azure so that you can later create a cloud account in Cloud.

You must have already purchased an Azure subscription, obtained a tenant and have an Azure user account.

---

Azure documentation can be found at Quickstart: Register an application with the Microsoft identity platform.

Register the Cloud web application with the Azure Active Directory and create a client secret key. Manage access to the newly create application by assigning a role. Also, obtain your Azure tenant ID and subscription ID. Once this task is complete, you should have the following information stored in a file:

- Application ID generated when registering Cloud with the Azure Active Directory.
- Client secret key generated for the newly registered Cloud application.
- Subscription ID
- Tenant ID

This information is necessary to create a cloud account in Cloud.

1. Log in to to your Microsoft Azure account.

Register Cloud to the Azure Active Directory.

2. Using the search box, enter app reg. A list of search results is listed.
3. Under Services, click App registrations.
4. Click New registration.
5. Enter the following to register Cloud to the Azure Active Directory:
  - a. For Name, enter the name of the application.  
The name can be anything meaningful to your organization, e.g., pc\_cloudapp.
  - b. For Supported account types, choose the option that best suits your organization. Click the Help me choose link for additional information about the available options.
  - c. For Redirect URI, select Web and enter the URL `https://hostname:9500/pc`.  
where hostname is the hostname of the machine where the Cloud Web Interface is installed. This is the URL that is used to log in to Cloud.
6. Click Register.

Once the application registration is complete, its details are displayed, including an Application ID.

Obtain the application id of the newly registered application.

7. Hover over the Application (client) ID and click the copy-to-clipboard icon when it appears.
8. Store the Application ID to a file.

The Application ID is used later to create a cloud account in Cloud.

Create a client secret key for your newly registered application.

9. Under, Manage, click Certificates and secrets.

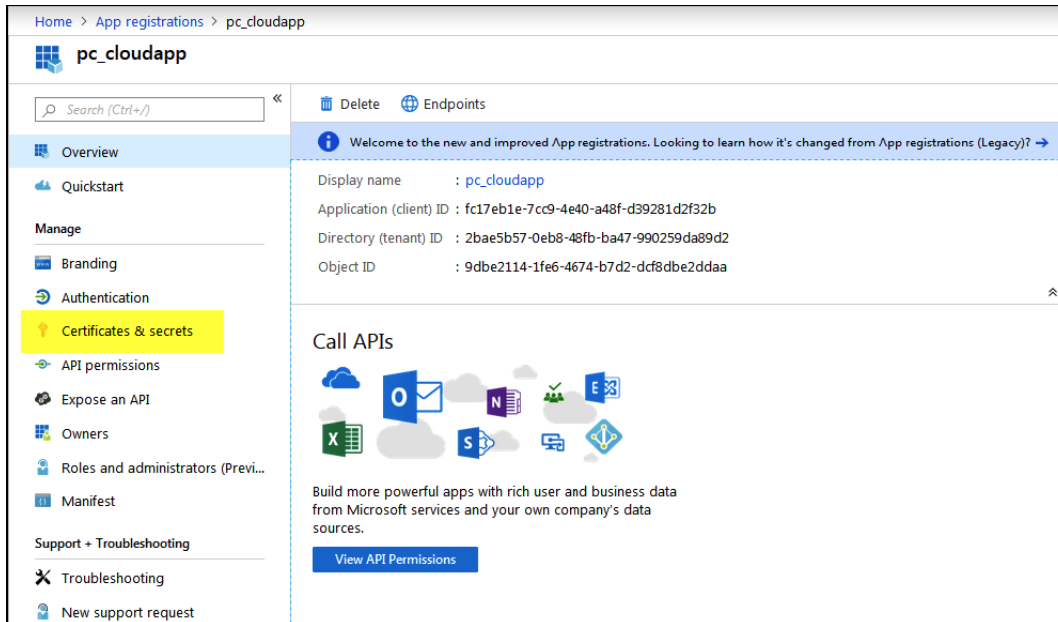

Figure 3-12: Certificates and Secrets

10. Under Client secrets, click New client secret.
11. Enter the following to add a client secret:
  - a. For DESCRIPTION, enter pc\_client\_secret.
  - b. For EXPIRES, select Never.
12. Click Add.

A client secret key is generated and is displayed under the heading VALUE.

13. Click next to the client secret key.
14. Store the client secret key to a file.

The client secret key is used later to create a cloud account in Cloud.

Obtain your Azure subscription ID.

15. Using the search box, enter subscription. A list of search results is listed.
16. Under Services, click Subscriptions.
17. Locate and click your subscription.

Details about the subscription are displayed, including a Subscription ID.

18. Hover over the Subscription ID and click when it appears.
19. Store the Subscription ID value to a file.

The Subscription ID is used later to create a cloud account in Cloud.

Assign an access control role to the newly registered application.

20. Click Access control (IAM).

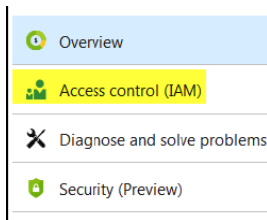

Figure 3-13: Add Access Controls

21. Click Add.
22. Click Add role assignment.
23. In the Add role assignment panel, enter the following to assign a role to the newly registered application:
  - a. For Role, select Contributor.
  - b. For Assign access to, select Azure AD user, group, or service principal.
  - c. For Select, search for the newly registered application by entering its name, e.g., pc\_cloudapp.
  - d. Select the application by clicking on it.
24. Click Save.

Obtain your Azure tenant ID:

25. At the top of the web page, click ?.
26. Click Show diagnostics.
27. Open the file using any text editor.
28. Search for tenantId.
29. Store the value of tenantId to a file.

The Tenant ID is used later to create a cloud account in Cloud

### 3.3.2 Add a Microsoft Azure Cloud Account

Add an Azure cloud account to Cloud so that you can create a cloud bursting scenario or an appliance. You should have the following information stored in a file:

- Application ID generated when registering Cloud with the Azure Active Directory.
- Client secret key generated for the newly registered Cloud application.
- Subscription ID
- Tenant ID

This information is necessary to create a cloud account in Cloud. If you do not have this information see Register the Cloud Application with Azure.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.
4. Click 

5. Enter the following to add a cloud account:
  - a. For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., azure\_cloudaccount.
  - b. For Client ID, enter the Application ID generated when Cloud was registered with the Azure Active Directory.
  - c. For Secret Key, enter the client secret key generated for the newly registered Cloud application.
  - d. For AD tenant ID, enter your Azure tenant ID.
  - e. For Subscription ID, enter your Azure subscription ID.
6. Click Create account.

### 3.3.3 Create a Resource Group

Create a resource group that will contain a virtual network and a virtual machine for cloud bursting. You must have already purchased an Azure subscription and have an Azure user account.

Azure documentation can be found at [Manage Azure resources through portal](#).

A resource group is container that holds related resources for an Azure solution. The resource group can include all the resources for the solution, or only those resources that you want to manage as a group. You decide how you want to allocate resources to resource groups based on what makes the most sense for your organization. Once the resource group is created, resources that are placed into the resource group are a virtual network, a virtual machine, and an image of the virtual machine.

1. Log in to your Microsoft Azure account.
2. Using the search box, enter resource groups. A list of search results is listed.
3. Under Services, click Resource Groups.
4. Click Add.
5. Enter the following to configure the basic settings for the resource group:
  - a. For Project Details enter the following:
    - For Subscription, choose the subscription to be billed for the use of the VM.
    - For Resource group, enter a name for the resource group.  
The name can be anything meaningful to your organization, e.g., bursting\_resource\_group.
  - b. For Resource Details enter the following:
    - For Region, select a location based on the geographical location of users.
6. Click Review + create.
7. Click Create.

It may take a moment to create the resource group. All resources (networks, virtual machines, etc.) that are created are placed within this resource group. The name of the resource group is required for creating a bursting scenario in Cloud.

### 3.3.4 Create a Virtual Network

Create a virtual network so that you can later create a virtual machine for cloud bursting. You must have already created a resource group.

Azure documentation can be found at [Virtual Network Documentation](#).

1. Log in to your Microsoft Azure account.
2. Using the search box, enter virtual networks. A list of search results is listed.
3. Under Services, click Virtual networks.
4. Click Add.
5. For Name, enter a name for the virtual network.  
The name can be anything meaningful to your organization, e.g., `bursting_virtual_network`
6. For Address space, enter an address range for the network using CIDR notation.
7. For Subscription, select the same subscription as was selected for the previously created resource group.
8. For Resource group, select the previously created resource group.
9. For Location, select the same geographical location as was selected for the previously created resource group.
10. For Subnet, enter the following:
  - a. For Name, enter a name for the virtual machine's subnet.  
The name can be anything meaningful to your organization, e.g., `bursting_subnet`
  - b. For Address range, enter an address range for the subnet in CIDR notation.
11. Click Create.

It may take a moment to create the virtual network. The name of the virtual network is required for creating a bursting scenario in Cloud.

### 3.3.5 Create a Virtual Machine

Create a virtual machine in Azure.

You must have already created a virtual network.

You may want to view the following web page to learn about Azure Managed Disks before creating a VM. Additionally, a video is available from Microsoft that shows how to create a virtual machine: [Create a Linux Virtual Machine](#).

1. Log in to your Microsoft Azure account.
2. Using the search box, enter virtual machines. A list of search results is listed.
3. Under Services, click Virtual machines.
4. Click Add.

Enter the following to configure the basic settings for the virtual machine:

- 
5. For Project Details enter the following:
    - a. For Subscription, choose the subscription to be billed for the use of the VM.
    - b. For Resource group, choose the previously created resource group.
    - c. For Virtual machine name, enter a name for the virtual machine.  
The name can be anything meaningful to your organization, e.g., bursting-vm.
    - d. For Region, select the same geographical location as was selected for the previously created resource group.
    - e. For Availability options, choose No infrastructure redundancy required.
    - f. For Image, click the Browse all public and private images link.
    - g. Using the search box:
      - On Linux platforms, enter CentOS 7 or RHEL 7 and press ENTER.
      - On Windows platforms, enter Windows and press ENTER.
    - h. Locate the appropriate image and select it.
      - On Linux platforms, cloud bursting has been tested on CentOS 7.2 - 7.6.
      - On Windows platforms, cloud bursting has been tested on Windows 10 and Windows Server 2012.
    - i. For Size, click the Change size link and select a machine size appropriate for your site's workload based on:
      - the number of cores
      - the amount of memory
      - storage
      - network performance

Consider the nature of the applications that you plan to deploy on the instance, the number of users that you expect to use the applications, and also how you expect the load to scale in the future. Remember to also factor in the CPU and memory resources that are necessary for the operating system.
    - j. Click Select.
  6. For Administrator Account, enter a user account :

This user will have sudo rights and will be able to connect to the VM to install the PBS MoM.

    - On Linux platforms:
      - For Authentication type, enable SSH public key.
      - For Username, enter a username of a user account that exists on your site's PBS Server.
      - For SSH public key, copy the SSH public key (i.e., id\_rsa.pub) of the user account and paste it.
    - On Windows platforms:
      - For Username, enter a username.
      - For Password, enter a password.
  7. For Inbound Port Rules, enter the following:
    - a. For Public inbound ports, enable Allow selected ports.
    - b. For Select inbound ports:
      - For Linux platforms, enable SSH (22).
      - For Windows platforms, enable RDH (3389).
  8. Click Next.

Enter the following to configure the storage settings for the virtual machine:

9. For Disk Options, enter the following:

- a. For OS disk size, choose an appropriate disk size based on your site's needs.
- b. For OS disk type, choose one of the following options:
  - Premium SSD
  - Standard SSD
  - Standard HDD

Choose SSD for I/O-intensive applications, where low latency and high throughput are critical. For testing, consider HDD to keep costs down, as you scale up and down quickly.

1. For Advanced, enter the following:

- a. Click Advanced.
- b. For Use managed disks, choose one of the following options:
  - Yes to use managed disks.
  - No to not use managed disks.

Enable this feature to have Azure automatically manage the availability of disks to provide data redundancy and fault tolerance, without creating and managing storage accounts on your own. This option is recommended by Azure as it is a lot more scalable.

1. Click Next.

Enter the following to configure the networking settings for the virtual machine:

2. For Network Interface, enter the following:

- For Virtual network, choose the virtual network previously created.

3. Click Review + create.

4. Click Create.

It may take a few minutes for the VM to be deployed. You will use this virtual machine to create an OS image.

Once the virtual machine is deployed a message is displayed indicating success, click on Go to resource.

### 3.3.6 Install the PBS MoM on the VM

Install the PBS Professional MoM on the virtual machine and configure the VM per your site's environment.

#### 3.3.6.1 Install the PBS MoM on the Linux VM

Install the PBS MoM on the Linux virtual machine and configure the VM per your site's environment. Use SSH to connect to the virtual machine. For more information see [Connect to your VM on Linux](#).

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the [Cloudinit Documentation](#).

The PBS Professional installer package will need to be copied to the virtual machine. Use SCP to copy the tarball file from the PBS Server to the virtual machine. For more information, see Move files to and from a Linux VM using SCP.

1. Log in to your site's PBS Server as the user account (username and the public SSH key) provided during the creation of the VM.
2. SSH into the virtual machine using the public IP address of the VM:

```
ssh IPV4PublicIP
```

where IPV4PublicIP is the public IP address of the virtual machine.

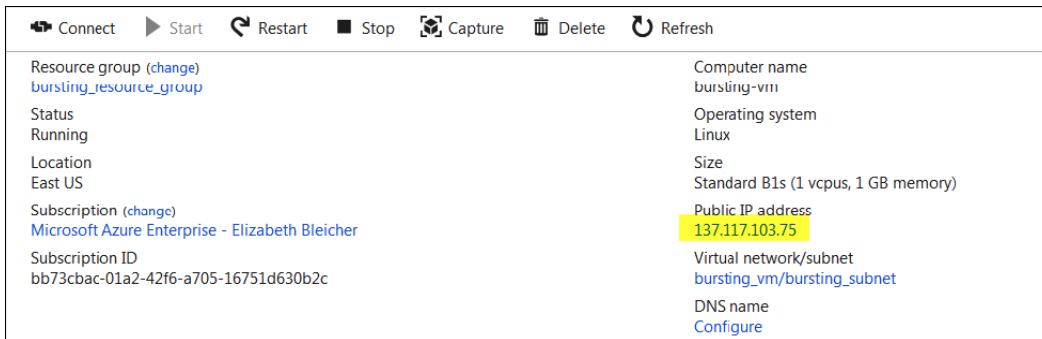

Figure 3-14: Bursting Virtual Machine

3. Enter the command:  

```
sudo -i
```
4. Copy the PBS Professional installation package to the VM.
5. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
6. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
7. Install cloud-init.
8. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.3.6.2 Install the PBS MoM on the Windows VM

Install the PBS MoM on the Windows virtual machine and configure the VM per your site's environment.

Use an RDP client to access the virtual machine. A connection can be established to the Windows virtual machine through the Azure portal. For more information see How to connect and sign on to an Azure virtual machine running Windows.

The PBS Professional installer package will need to be copied to the virtual machine. Use RDP to map a local drive to gain access to the installer package.

1. Log in to the Azure portal.
2. Using the search box, enter virtual machines.
3. Under Services, click Virtual machines.
4. Select the Windows virtual machine created for cloud bursting by clicking its name.
5. Click Connect.
6. Click the RDP tab.
7. Click Download RDP File.

8. Open the file.
9. Click Connect.
10. Enter the password that was established for the Administrator Account when creating the virtual machine.
11. Click OK.
12. Click Yes to connect even if there are certificate errors.  
A connection is established with the Windows virtual machine.
13. Copy the PBS Professional installation package to the VM.
14. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
15. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
16. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.3.7 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

#### 3.3.7.1 Create a Linux OS Image

Create an image of the Linux virtual machine configured per your site's requirements.

You must have already create a virtual machine, installed the PBS MoM on the VM and configured the VM per your site's environment.

To create an OS image requires the Azure CLI. Refer to these instructions for installing the CLI [How to install the Azure CLI](#). It is recommended to install the CLI on a Windows or Mac machine and then use the command prompt to execute the CLI commands.

Before you can create an OS image of the previously created VM, you must first SSH into the VM and deprovision it. Next you will use the Azure CLI to deallocate and generalize the VM and then create the image. Generalizing the virtual machine removes any SSH keys and DNS settings from the VM.

Follow Step 1 and Step 2 as documented at the URL [How to create an image of a virtual machine or VHD to create an image of the VM](#).

Before you can deallocate the virtual machine you may have to execute the following commands to set your subscription to be the active subscription:

```
az account list
az account set --subscription <your subscription ID>
```

You can now delete the virtual machine so that you are no longer charged for it.

#### 3.3.7.2 Create a Windows OS Image

Create an image of the Windows virtual machine configured per your site's requirements.

You must have already create a virtual machine, installed the PBS MoM on the VM and configured the VM per your site's environment.

The VM must first be generalized using Sysprep. For more information see [Create a managed image of a generalized VM in Azure](#).

1. Log in to the Azure portal.
2. Using the search box, enter virtual machines.

3. Under Services, click Virtual machines.
4. Select the Windows virtual machine created for cloud bursting by clicking its name.
5. Click Connect.
6. Click the RDP tab.
7. Click Download RDP File.
8. Open the file.
9. Click Connect.
10. Enter the password that was established for the Administrator Account when creating the virtual machine.
11. Click OK.
12. Click Yes to connect even if there are certificate errors.
13. Open a Command Prompt window as an administrator.
14. Using Windows Explorer, navigate to the directory C:\Windows\System32\Sysprep.
15. Right-click sysprep.exe and select Run as Administrator.
16. For System Cleanup Action, choose Enter System Out-of-Box Experience (OOBE).
17. Enable the Generalize check box.
18. For Shutdown Options, choose Shutdown.
19. Click OK.
20. Once the VM is shutdown, close the RDP session.
21. Navigate to the browser window where the Azure portal is open and the VM details are displayed.
22. Click Capture.
23. For name, enter a name for the image.

The name of the image should contain the string “windows” (case insensitive). For example, Windows Server 2012 R2 Datacenter.
24. For Resource group, choose the previously created resource group.
25. For Type the virtual machine name, enter the name of the VM.
26. Click Create.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.3.8 Create an Azure Cloud Bursting Scenario

Create an Azure bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to your Microsoft Azure account. Open a second browser window and log in to Cloud.

Before creating a cloud bursting scenario, read the following Azure article about scale sets [What are virtual machine scale sets](#).

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. On Windows platforms, the startup script must be a PowerShell script. For more information see [PowerShell Scripting](#). On Linux platforms, use a cloud-init script.

Note: To create a bursting scenario you must enter a resource group, however the resources necessary for creating the bursting scenario (network, subnet, network security group and the OS image) can all reside in a different resource group. However, the resource groups must be in the same geographic location for this to work.

For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created Azure cloud account from the list.
  - d. For Select a region, select the same geographic location as was selected for the previously created bursting resource group.
6. Click Next.

Enter information about the Azure resources necessary to burst in the cloud.

7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.

If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the Azure browser window.
10. In the menu located on the left-hand side of the web page, click Resource Groups.
11. Copy the name of the resource group created for cloud bursting.
12. Navigate to the Cloud browser window.
13. For Resource group name, paste the resource group copied from Azure.
14. Navigate to the Azure browser window.
15. In the menu located on the left-hand side of the web page, click Virtual Networks.
16. Copy the name of the virtual network created for cloud bursting.
17. Navigate to the Cloud browser window.
18. For Network name, paste the name of the virtual network copied from Azure.

If the network is contained in a resource group that is different from the one entered for the bursting scenario, it must be entered as Resource Group Name/Virtual Network Name.
19. Navigate to the Azure browser window.
20. Select the virtual network created for cloud bursting.

21. Click Subnets.

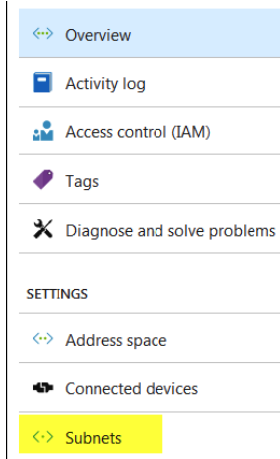

Figure 3-15:Subnet

22. For Subnet name, copy the name of the subnet created for the cloud bursting virtual network.
23. Navigate to the Cloud browser window.
24. For Subnet name, paste the Subnet copied from Azure.  
If the subnet is contained in a resource group that is different from the one entered for the bursting scenario, it must be entered as Resource Group Name/Subnet Name.
25. Navigate to the Azure browser window.
26. In the menu located on the left-hand side of the web page, click Resource Groups.
27. Select the Resource Group created for cloud bursting.
28. In the list, locate the Network Security group created for cloud bursting. The Type is Network Security group.
29. Copy the name of the network security group.
30. Navigate to the Cloud browser window.
31. For Network security group name, paste the network security group copied from Azure.  
If the network security group is contained in a resource group that is different from the one entered for the bursting scenario, it must be entered as Resource Group Name/Network Security Group Name.
32. Choose one of the following options based on whether you chose to use the Azure managed disk feature when creating the virtual machine:
  - Enable Managed Storage if you enabled the managed disk feature.
  - Disable Managed Storage if you disabled the managed disk feature.
33. Navigate to the Azure browser window.
34. In the menu located on the left-hand side of the web page, click Resource Groups.
35. Select the Resource Group created for cloud bursting.
36. In the list, locate the image that was created for cloud bursting. The Type is Image.
37. Select the image.

38. Choose one of the following options:

- If you chose to use managed disks when you created the VM, copy the name of the image.
- If you did not choose to use managed disks when you created the VM, copy the Linux Source BLOB URI.

39. Navigate to the Cloud browser window.

40. For OS image, paste the information copied from Azure.

If the OS image is contained in a Resource group that is different from the one entered for the bursting scenario, it must be entered as Resource Group Name/OS Image Name or Resource Group Name/URI.

41. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.

It is recommended to leave this disabled.

42. For Maximum number of VMs inside a ScaleSet, specify the limit for your cloud bursting scenario.

If you use InfiniBand, Azure limits the number of VMs on a scaleset to 100. Without InfiniBand, for a scaleset with managed disk and custom image, you can specify a higher limit.

43. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.

44. Add public SSH keys for any users that you want to have access to the burst nodes:

- Log in to the PBS Server.
- Copy the public SSH key for the user.  
Public key files are usually stored in `/.ssh` in the user's home directory.
- Navigate to the Cloud browser window.
- Click Add to add the public key.
- For Public SSH keys, paste the public SSH key.
- Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.

45. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.

It is expressed as an integer whose units are in seconds.

46. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as `key:value`. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

Figure 3-16:Key-Value Tag

47. Repeat the previous step to add more tags.

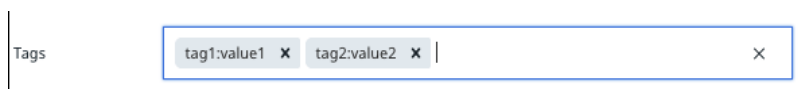

Figure 3-17: Additional Tags

48. Click Next.

49. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

50. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.4 Configure Google Cloud Platform Cloud Bursting

Create the necessary components in GCP that are required for cloud bursting and then create a Cloud cloud bursting scenario.

### 3.4.1 Create a Project

Create a GCP Project so that you can create the necessary cloud components for cloud bursting. GCP documentation can be found at [Creating and Managing Projects](#).

Google Cloud Platform projects form the basis for creating, enabling, and using all Cloud Platform services including managing APIs, enabling billing, adding and removing collaborators, and managing permissions for Cloud Platform resources.

1. Log in to the GCP console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Home.
4. Click Create.
5. For Project Name, enter a name for the project.

The name can be anything meaningful to your organization, e.g., pc\_cloudproject.

6. Click Create.

It may take a few moments to create the project.

7. Using a browser, navigate to the following URL: <https://console.developers.google.com/apis/library/compute.googleapis.com?project=PROJECTNAME>

where PROJECTNAME is the name of the project.

8. Click Enable.

### 3.4.2 Create a Service Account

Create a Google Cloud Platform service account so that you can later create a cloud account in Cloud. You must already have signed up for an GCP account.

GCP documentation can be found at [Understanding Service Accounts and Compute Engine IAM Roles](#).

A service account is a special Google account that belongs to an application or a virtual machine, instead of to an individual end user. Create a service account and give this account administrative permissions for all Compute Engine resources. Once this task is complete, you should have downloaded a JSON file containing the following:

- Project ID
- Client ID
- Client email
- Private key ID
- Private key

This information is necessary to create a cloud account in Cloud.

1. Log in to the GCP console.
2. Click  located in the upper left-hand corner of the web page.
3. Click IAM & admin > Service accounts.
4. Click CREATE SERVICE ACCOUNT.
5. Enter the following to create a service account:
  - a. For the Service account name, enter a name for the service account.  
The name can be anything meaningful to your organization, e.g., pc-service-account.
  - b. Click CREATE.
  - c. For the Project role, click Select a role > Compute Engine > Compute Admin. This role gives full control of all Compute Engine resources.
  - d. Click CONTINUE.
  - e. Under Create key (optional), click CREATE KEY.
  - f. For Key type, enable JSON.
  - g. Click CREATE.
  - h. Save the JSON file in a secure location.  
The information in this file is used later to add a cloud account to Cloud.
  - i. Click CLOSE.
  - j. Click DONE.  
The service account is created.

### 3.4.3 Add a GCP Cloud Account

Add an existing GCP service account to Cloud so that you can create a cloud bursting scenario or an appliance.

You must have created a GCP service account, given it Compute Admin permissions and downloaded a JSON file containing information about the service account. The information in the JSON file is necessary to create a cloud account in Cloud. If you do not have this information see [Create a Service Account](#).

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.
4. Click .
5. Enter the following to add a cloud account:
  - a. For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., gcp\_cloudaccount.
  - b. For Project ID, copy and paste the project\_id value from the JSON file.
  - c. For Client ID, copy and paste the client\_id value from the JSON file.
  - d. For Client Mail, copy and paste the client\_email value from the JSON file.
  - e. For Private Key ID, copy and paste the private\_key\_id value from the JSON file.
  - f. For Private Key, copy and paste the private\_key value from the JSON file.  
Do not copy the \n characters at the end of the private\_key value.
6. Click Create account.

### 3.4.4 Create a Virtual Private Cloud Network

Create a Virtual Private Network (VPC) in GCP so that you can later create a virtual machine for cloud bursting. GCP documentation can be found at [Virtual Private Cloud Documentation](#) and [Using VPC Networks](#).

1. Log in to the GCP console.
2. Click  located in the upper left-hand corner of the web page.
3. Click VPC network > VPC networks.
4. Click CREATE VPC NETWORK.
5. Enter the following to create a VPC:
  - a. For the Name, enter a name for the VPC.  
The name can be anything meaningful to your organization, e.g., bursting-vpc.
  - b. In the Subnets section, click the Custom tab under Subnet creation mode.
  - c. For Name, enter a name for the subnet.  
The name can be anything meaningful to your organization, e.g., bursting-subnet.
  - d. For Region, select a Region based on the geographical location of users.
  - e. For IP address range, enter an IP address range using CIDR notation
  - f. For Private Google access, enable Off.
  - g. Click Done.
  - h. For Dynamic routing mode, enable Regional.
6. Click Create.  
Creating the VPC network may take some time. Do not proceed until the VPC is created.

7. Select the VPC by clicking on its name.
8. Click the Firewall rules tab.
9. Click CREATE FIREWALL RULE.
10. Enter the following to create a firewall rule:
  - a. For Name, enter a name for the firewall rule.  
The name can be anything meaningful to your organization, e.g., ssh-all.
  - b. For Direction of Traffic, enable Ingress.
  - c. For Action on match, enable Allow.
  - d. For Targets, select All instances in the network.
  - e. For Source filter, select IP ranges.
  - f. For Source IP ranges, enter 0.0.0.0/0.
  - g. For Protocols and ports, enable Specified protocols and ports.
  - h. Enable tcp.
  - i. Enter 22.
11. Click Create.

### 3.4.5 Create a Virtual Machine

Create a CentOS 7.3 virtual Machine in GCP.

You must have already created a virtual network with a subnet and added a firewall rule.

GCP documentation can be found at [Virtual Machine Instances and Creating and Starting a VM Instance](#).

1. Log in to the GCP console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Compute Engine > VM instances.
4. Click CREATE INSTANCE.

5. Enter the following to create a virtual machine:

- a. For the Name, enter a name for the virtual machine.  
The name can be anything meaningful to your organization, e.g., bursting-vm.
- b. For Zone, select a zone that is in the same Region as the subnet of the previously created VPC.
- c. In the Machine type, click the Customize link.

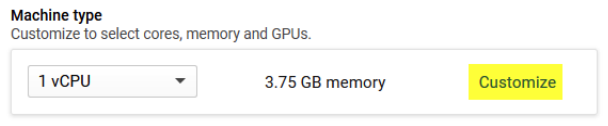

Figure 3-18:Customize the Machine Type

- d. Specify the CPUs, GPUs and RAM.  
Consider the nature of the applications that you plan to deploy on the instance, the number of users that you expect to use the applications, and also how you expect the load to scale in the future. Remember to also factor in the CPU and memory resources that are necessary for the operating system.
  - e. For Boot disk, click Change.
  - f. Choose CentOS 7.
  - g. For Boot disk type, choose one of the following options:
    - Standard persistent disk
    - SSD persistent disk

Choose SSD for I/O-intensive applications, where low latency and high throughput are critical. For testing, consider Standard persistent disk to keep costs down.
  - h. For Size, specify the size of the boot disk.
  - i. Click Select.
  - j. Under Identity and API access, for Service Account, select No service account.
  - k. For Firewall, choose Allow HTTP traffic.
  - l. Click Management, disks, networking, SSH Keys.
  - m. Click the Networking tab.
  - n. Click Add network interface.
  - o. For Network, choose the VPC you previously created for bursting.
  - p. For Network Service Tier, click Standard.
  - q. Click Done.
  - r. Delete any default network interfaces that might have been automatically generated.
  - s. Click the Security tab.
  - t. For SSK Keys, copy the SSH public key (i.e., id\_rsa.pub) of a user account that exists on your site's PBS Server and paste it.  
This user will have sudo rights and will be able to SSH into the VM to install the PBS MoM.
6. Click Create.  
Creating the virtual machine may take some time.

### 3.4.6 Install and Configure the PBS MoM on the VM

Install the PBS MoM on the virtual machine and configure the VM per your site's environment.

The username for logging into the virtual machine is determined by the SSH key that was provided during the creation of the virtual machine.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

1. Log in to your site's PBS Server as the user account (public SSH key) provided during the creation of the VM.
2. SSH into the virtual machine using the public IP address of the VM:

```
ssh IPV4PublicIP
```

where IPV4PublicIP is the public IP address of the virtual machine.

<input type="checkbox"/>	Name ^	Zone	Recommendation	Internal IP	External IP	Connect
<input type="checkbox"/>	bursting-vm	us-east1-b		10.1.0.2 (nic0)	35.231.82.235	SSH

Figure 3-19: Bursting Virtual Machine

3. Enter the command:

```
sudo -i
```

4. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
5. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
6. Install cloud-init.
7. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.4.7 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

You must have already create a virtual machine, installed the PBS MoM on the VM and configured the VM per your site's environment.

GCP documentation can be found at Creating, Deleting, and Deprecating Custom Images.

1. Log in to the GCP console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Compute Engine > VM instances. A list of virtual machines is displayed.
4. Click the three vertical dots next to the virtual machine that was created for cloud bursting.

<input type="checkbox"/>	Name ^	Zone	Recommendation	Internal IP	External IP	Connect
<input type="checkbox"/>	bursting-vm	us-east1-b		10.1.0.2 (nic0)	35.231.82.235	SSH

Figure 3-20: Bursting Virtual Machine

5. Click Stop.

It may take some time for the VM to be stopped. Do not proceed until the VM is stopped.

6. In the menu located on the left-hand side of the web page, click Images .
7. Click CREATE IMAGE.
8. Enter the following to create an image:
  - a. For Name, enter a name for the image.  
The name can be anything meaningful to your organization, e.g., bursting-image.
  - b. For Source select Disk.
  - c. For Source disk, select the previously created virtual machine.
9. Click Create.  
It may take some time to create the image. Do not proceed until the image is created.  
You can now delete the virtual machine so that you are no longer charged for it.

### 3.4.8 Create a GCP Cloud Bursting Scenario

Create an GCP bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to your GCP console. Open a second browser window and log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. Use a cloud-init script for the startup script. For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created GCP cloud account from the list.
  - d. For Select a region, select the same geographic location as was selected for the previously created bursting VPC.
6. Click Next.

Enter information about the GCP resources necessary to burst in the cloud.

7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.  
If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the GCP browser window.
10. Click  located in the upper left-hand corner of the web page.
11. Click VPC network > VPC networks.
12. Click on the name of the VPC that was created for cloud bursting. VPC network details are displayed.

13. Copy the name of the VPC network.
14. Navigate to the Cloud browser window.
15. For Network name, paste the name of the VPC network copied from GCP.
16. Navigate to the GCP browser window.
17. Copy the name of the VPC network subnet.
18. Navigate to the Cloud browser window.
19. For Subnetwork name, paste the name of the VPC network subnet copied from GCP.
20. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.  
It is recommended to leave this disabled.
21. Navigate to the GCP browser window.
22. Click  located in the upper left-hand corner of the web page.
23. Click Compute Engine > Images.
24. Select the image created for cloud bursting.
25. Click Equivalent REST
26. Copy the value for the entry called selfLink.
27. Navigate to the Cloud browser window.
28. For OS Image URI, paste the link copied from GCP.
29. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.
30. Add public SSH keys for any users that you want to have access to the burst nodes:

- a. Log in to the PBS Server.
- b. Copy the public SSH key for the user.  
Public key files are usually stored in /.ssh in the user's home directory.
- c. Navigate to the Cloud browser window.
- d. Click Add to add the public key.
- e. For Public SSH keys, paste the public SSH key.
- f. Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.

31. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.

It is expressed as an integer whose units are in seconds.

32. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as key:value. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

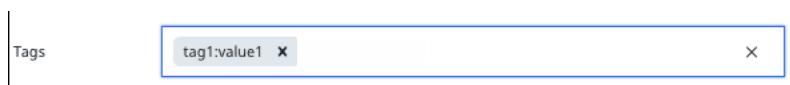

Figure 3-21:Key-Value Tag

33. Repeat the previous step to add more tags.

Figure 3-22:Additional Tags

34. Click Next.
35. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

36. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.5 Configure Oracle Cloud Platform Cloud Bursting

Create the necessary components in Oracle Cloud that are required for cloud bursting and then create a Cloud cloud bursting scenario.

### 3.5.1 Create an Oracle Cloud User Account

Create an Oracle Cloud user account so that you can later create a cloud account in Cloud. You must already have signed up for an Oracle Cloud account and have an associated tenancy. Oracle documentation can be found at Adding Users and Resource Identifiers.

An Oracle user account must be created to add an Oracle cloud account to Cloud. Once this task is complete, you should have the following information stored in a file:

The user account's Oracle Cloud ID (OCID).

This information is necessary to create a cloud account in Cloud.

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Identity > Users.
4. Click Create User.

5. Enter the following to create the user:
  - a. For NAME, enter a name for the user.  
The name can be anything meaningful to your organization, e.g., pc\_clouduser.
  - b. For DESCRIPTION, enter a description of the user.
6. Click Create.  
The user account is created and displayed in the users list.
7. Click Show located under the name of the user. The user account's OCID is displayed.
8. Click Copy to copy the OCID.
9. Store the OCID to a file.  
The OCID is used later to create a cloud account in Cloud.
10. Click Group from the menu located on the left-hand side of the web page.
11. Click Create Group.
12. Enter the following:
  - a. For Name, enter Administrators.
  - b. For Description, enter a description for the group.
  - c. Click Submit.The group is created and is displayed in the Groups list.
13. Click on the name of the group.
14. Click Add User to Group.
  - a. For User, select the user that was previously created (e.g., pc\_clouduser).
  - b. Click Add.
15. Click  located in the upper left-hand corner of the web page.
16. Click Identity > Policies.
17. Click Create Policy.
  - a. For Name, enter a name for the policy.
  - b. For Policy Versioning, enable Keep Policy Current.
  - c. For Policy Statements, enter: ALLOW GROUP Administrators to manage all-resources IN TENANCY
  - d. Click Create.

### 3.5.2 Generating an SSH Public for the Oracle Cloud User

Use OpenSSL to create a private and public key in a PEM format for the previously created Oracle Cloud user.

If you're using Windows, you'll need to install Git Bash for Windows and run the commands with that tool.

Use OpenSSL to generate an API signing key pair in a PEM format. Once this task is complete, you should have the following information stored in a file:

- The RSA public key's fingerprint.
1. Generate a private key by executing the following command:  
`openssl genrsa -out oracle_private_key.pem 2048`

We recommend changing the permissions on this file so that only you have read/write access.

The private key is used later to create a cloud account in in Cloud.

Generate the public key by executing the following command:

```
openssl rsa -pubout -in oracle_private_key.pem -out oracle_public_key.pem
```

2. Log in to the Oracle Cloud Infrastructure console.
3. Click  located in the upper left-hand corner of the web page.
4. Click Identity > Users.
5. Click the name of the previously created user (e.g., pc\_clouduser).
6. Click Add Public Key.
7. Copy and paste the contents of the public RSA key file.
8. Click Add.

A fingerprint is generated.

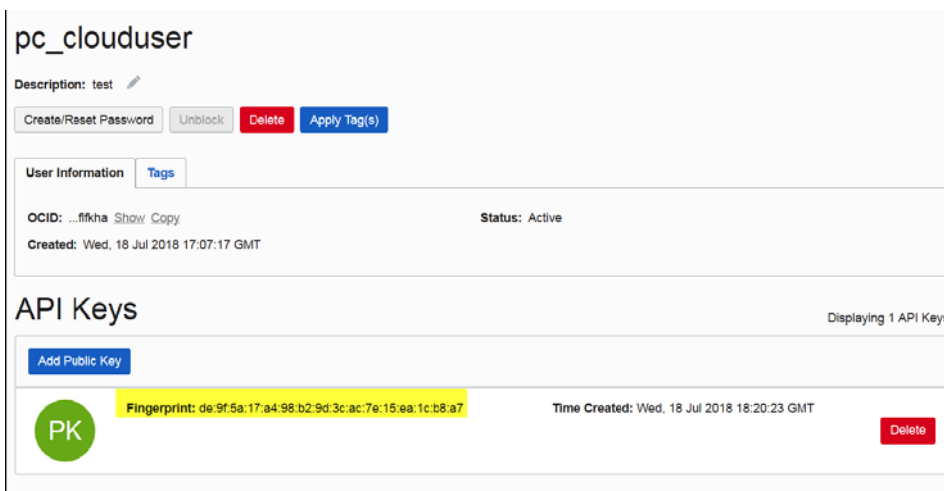

Figure 3-23:Public Key Fingerprint

9. Copy the fingerprint.
10. Store the fingerprint to a file.

The fingerprint is used later to create a cloud account in Cloud.

### 3.5.3 Obtain the Root Compartment Identifier

Obtain the Oracle Cloud identifier of the root compartment so that you can later create a cloud account in Cloud.

You must already have signed up for an Oracle Cloud account and have an associated tenancy. Oracle documentation can be found at Understand Compartments.

When your tenancy is provisioned, a root compartment is created for you. Compartments can be used to organize and isolate your resources to make it easier to manage and secure access to them. Your root compartment holds all of your cloud resources. You can think of the root compartment like a root folder in a file system. The first time you sign in to the Oracle Cloud Console and select a service, you will see your root compartment. All the resources required for cloud bursting will be contained in this root compartment. You will need the root compartment's resource identifier to add an Oracle cloud account to Cloud. Once this task is complete, you should have the following information stored in a file:

The compartment's Oracle Cloud ID (OCID).

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Identity > Compartments.
4. Click Show located under the name of the root compartment. The compartment's OCID is displayed.
5. Click Copy to copy the OCID.
6. Store the OCID to a file.

The OCID is used later to create a cloud account in Cloud.

### 3.5.4 Obtain the Tenancy Identifier

Obtain the Oracle Cloud identifier of the tenancy that you can later create a cloud account in Cloud. You must already have signed up for an Oracle Cloud account and have an associated tenancy.

You will need the tenancy's Oracle Cloud identifier to add an Oracle cloud account to Cloud. Once this task is complete, you should have the following information stored in a file:

The tenancy's Oracle Cloud ID (OCID).

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Administration > Tenancy Details.
4. Under Tenancy Information, click Show located to the right of OCID:

The tenancy's OCID is displayed.

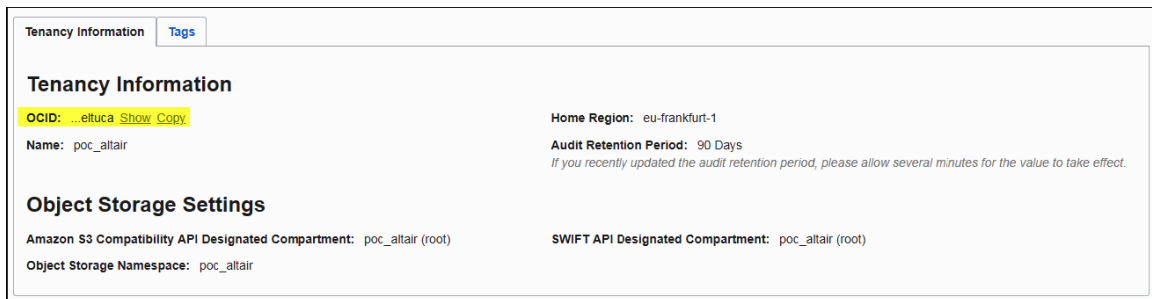

Figure 3-24: Tenancy OCID

5. Click Copy to copy the OCID.
6. Store the OCID to a file.

The OCID is used later to create a cloud account in Cloud.

### 3.5.5 Add an Oracle Cloud Account

Add an existing Oracle Cloud account to Cloud so that you can create a cloud bursting scenario or an appliance.

You must have created an Oracle Cloud user and added a public key for the user. You should have the following information stored in a file:

- User OCID generated when creating the Oracle user.
- Tenancy OCID.
- Root compartment OCID.
- Fingerprint of the public key generated for the Oracle user.
- RSA private key that was generated for the Oracle user.

This information is necessary to create a cloud account in Cloud. If you do not have this information see [Create an Oracle Cloud User Account](#), [Generating an SSH Public for the Oracle Cloud User](#), [Obtain the Root Compartment Identifier](#) and [Obtain the Tenancy Identifier](#).

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.
4. Click .
5. Enter the following to add a cloud account:
  - a. For Account name, enter any name for the cloud account.
  - b. The name can be anything meaningful to your organization, e.g., oracle\_cloudaccount.
  - c. For User OCID, enter the user OCID generated when creating the Oracle cloud user.
  - d. For Tenant OCID, enter the tenancy OCID .
  - e. For Compartment OCID, enter the root compartment OCID.
  - f. For Fingerprint, enter the fingerprint generated when adding the public SSH key for the Oracle user.
  - g. For Private Key, enter the generated RSA private key.
6. Click Create account.

### 3.5.6 Create a Virtual Cloud Network

Create a Virtual Cloud Network (VCN) so that you can perform cloud bursting.

You must already have signed up for an Oracle Cloud account and have an associated tenancy. Oracle documentation can be found at [Overview of Networking and Creating a Virtual Cloud Network](#). An Oracle VCN must be created to create a bursting scenario in Cloud.

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Networking > Virtual Cloud Networks.
4. Choose a region based on the geographical location of your users. Use the REGION pull-down menu.
5. Click Create Virtual Cloud Network.

6. Enter the following to create a VNC:

- For CREATE IN COMPARTMENT, select the root compartment.
- For NAME, enter a name for the VNC.  
The name can be anything meaningful to your organization, e.g., bursting\_vnc.
- Enable CREATE VIRTUAL CLOUD NETWORK PLUS RELATED RESOURCES.

Choosing this option automatically creates a VCN with a CIDR block 10.0.0.0/16, an internet gateway, a route rule to enable traffic to and from the internet gateway, the default security list, the default set of DHCP options, and one public subnet per availability domain.

7. Click Create Virtual Cloud Network.

A summary of the VNC, internet gateway, default route table and subnets is displayed.

8. Click Close.

A list of VNCs is displayed.

Subnets in pc\_compartment Compartment

Create Subnet

Sort by: Created Date (Desc)  Displaying 3 Subnets

	Public Subnet IPCG-PHX-AD-3 OCID: ...wvav8 <a href="#">Show</a> <a href="#">Copy</a>	CIDR Block: 10.0.2.0/24 Virtual Router MAC Address: 00:00:17:8A:A7:49	Availability Domain: IPCG-PHX-AD-3 DNS Domain Name: sub0730135... <a href="#">Show</a> <a href="#">Copy</a> Subnet Access: Public Subnet	Route Table: <a href="#">Default Route Table for bursting_vnc</a> Security Lists: <a href="#">Default Security List for bursting_vnc</a>	DHCP Options: <a href="#">Default DHCP Options for bursting_vnc</a> ***
	Public Subnet IPCG-PHX-AD-2 OCID: ...m6q8 <a href="#">Show</a> <a href="#">Copy</a>	CIDR Block: 10.0.1.0/24 Virtual Router MAC Address: 00:00:17:8A:A7:49	Availability Domain: IPCG-PHX-AD-2 DNS Domain Name: sub0730135... <a href="#">Show</a> <a href="#">Copy</a> Subnet Access: Public Subnet	Route Table: <a href="#">Default Route Table for bursting_vnc</a> Security Lists: <a href="#">Default Security List for bursting_vnc</a>	DHCP Options: <a href="#">Default DHCP Options for bursting_vnc</a> ***
	Public Subnet IPCG-PHX-AD-1 OCID: ...jtzka <a href="#">Show</a> <a href="#">Copy</a>	CIDR Block: 10.0.0.0/24 Virtual Router MAC Address: 00:00:17:8A:A7:49	Availability Domain: IPCG-PHX-AD-1 DNS Domain Name: sub0730135... <a href="#">Show</a> <a href="#">Copy</a> Subnet Access: Public Subnet	Route Table: <a href="#">Default Route Table for bursting_vnc</a> Security Lists: <a href="#">Default Security List for bursting_vnc</a>	DHCP Options: <a href="#">Default DHCP Options for bursting_vnc</a> ***

Figure 3-25: Virtual Machine Subnets and Associated Availability Domains

9. Click the name of the VNC.

The subnets are displayed. A subnet is created for each availability domain (data center) located in the previously selected region.

Next, create a virtual machine that is hosted in one of the region's availability domains.

### 3.5.7 Creating a Virtual Machine

Create a CentOS 7 virtual machine (VM) in Oracle Cloud.

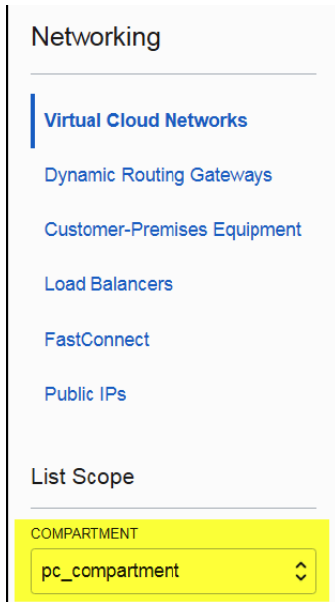

You must already have signed up for an Oracle Cloud account, have an associated tenancy and have created a VNC in a region that is geographically close to your users. The VNC should have a subnet associated to each of the region's availability domains. If you have not created a VNC see Create a Virtual Cloud Network.

Virtual machines are hosted in availability domains (data centers) located in a region and are based on predefined VM shapes. Before proceeding, determine the VM shape that your site requires for cloud bursting based on the number of CPUs, memory, disk space, network bandwidth, and virtual network

interface cards. While selecting the shape for a VM, consider the nature of the applications that you plan to deploy on the instance, the number of users that you expect to use the applications, and also how you expect the load to scale in the future. Remember to also factor in the CPU and memory resources that are necessary for the operating system.

Next, verify that your Oracle tenancy has the appropriate service limits for the VM shape and the region's availability domains. Check Tenancy Service Limits .

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Compute > Instances.
4. Choose the region where the previously created VNC is hosted. Use the REGION pull-down menu.
5. For COMPARTMENT, select the root compartment.

6. Click Create Instance.

7. Enter the following to create a virtual machine:
  - a. For NAME, enter a name for the VM.  
The name can be anything meaningful to your organization, e.g., `bursting_vm`.
  - b. For AVAILABILITY DOMAIN, choose one of the region's availability domains.  
The virtual machine is hosted in the chosen availability domain (data center). Choose the availability domain that best suits your site's cloud bursting requirements based on the machine type of the virtual machine (VM shape) and service limits.
  - c. For BOOT VOLUME, enable ORACLE-PROVIDED OS IMAGE.
  - d. For IMAGE OPERATING SYSTEM, choose CentOS 7.
  - e. For SHAPE TYPE, enable VIRTUAL MACHINE.
  - f. For SHAPE, select a VM shape.  
Choose the VM shape that best suits your site's cloud bursting requirements based on number of CPUs, memory, disk space, and network bandwidth.
  - g. For IMAGE VERSION, select the latest available one.
  - h. For BOOT VOLUME CONFIGURATION, enable CUSTOM BOOT VOLUME SIZE and enter a boot volume size in GBs.
  - i. Enable PASTE SSH KEYS and copy the SSH public key (i.e., `id_rsa.pub`) of a user account that exists on your site's PBS Server and paste it.  
This user will have sudo rights and will be able to SSH into the VM to install the PBS MoM.
  - j. For VIRTUAL CLOUD NETWORK, choose the VCN that was created for cloud bursting.
  - k. For SUBNET, choose the subnet associated with the previously chosen availability domain.
8. Click Create Instance.

Creating the virtual machine may take some time. It is done when the state is "Running".

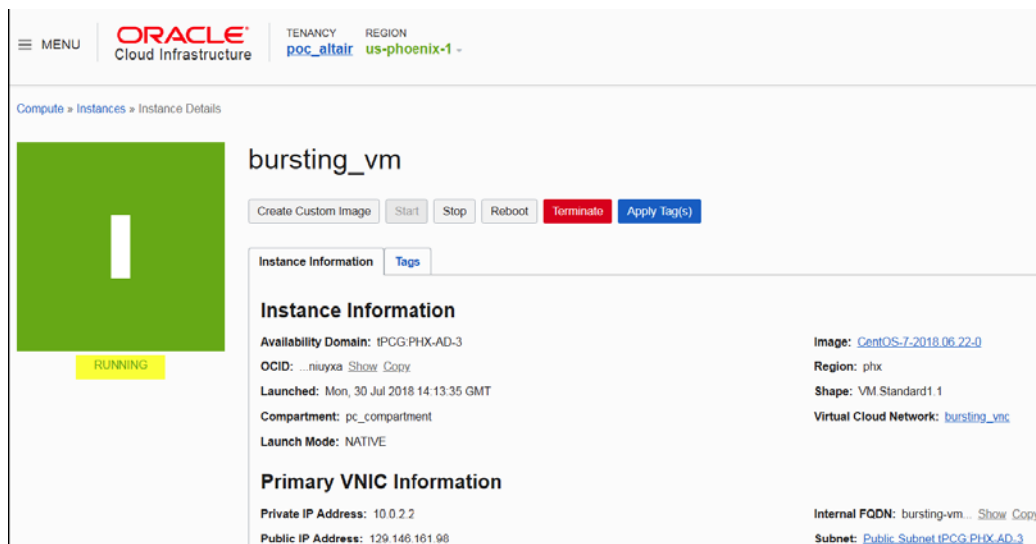

Figure 3-26:Running Virtual Machine

### 3.5.8 Check Tenancy Service Limits

Check the service limit for your tenancy before creating the components necessary for cloud bursting. You must already have signed up for an Oracle Cloud account and have an associated tenancy.

When you sign up for Oracle Cloud Infrastructure, a set of service limits are configured for your tenancy. The service limit is the quota or allowance set on a resource. For example, your tenancy is allowed a maximum number of compute instances (virtual machines) per availability domain. These limits are generally established with your Oracle sales representative when you purchase Oracle Cloud Infrastructure. Oracle documentation can be found at [Service Limits and Regions and Availability Domains](#).

When you reach the service limit for a resource, you receive an error when you try to create a new resource of that type. You cannot create a new resource until you are granted an increase to your service limit or you terminate an existing resource.

View your tenancy's limits to ensure that there are sufficient resources available in a region's availability domains.

1. Log in to the Oracle Cloud Infrastructure console.
2. Choose the region where the previously created VNC is hosted. Use the REGION pull-down menu.
3. Click  located in the upper left-hand corner of the web page.
4. Click Governance > Service Limits.
5. Scroll down to the Service Limits section.
6. Click Compute.

Availability domains (data centers) for the region are displayed. For each resource (VM shape) the number of nodes that can be burst in the corresponding availability domains are displayed. In the below example, three nodes can be burst in each data center in the us-phoenix-1 region for the VM Standard1.1 shape.

Resource	Region (us-phoenix-1)		tPCG:PHX-AD-1		tPCG:PHX-AD-2		tPCG:PHX-AD-3	
	Limit	Usage	Limit	Usage	Limit	Usage	Limit	Usage
Custom Images	25	0	n/a	n/a	n/a	n/a	n/a	n/a
VM.DenseIO1.16	n/a	n/a	0	0	0	0	0	0
VM.DenseIO1.4	n/a	n/a	1	0	1	0	1	0
VM.DenseIO1.8	n/a	n/a	0	0	0	0	0	0
VM.DenseIO2.16	n/a	n/a	0	0	0	0	0	0
VM.DenseIO2.24	n/a	n/a	0	0	0	0	0	0
VM.DenseIO2.8	n/a	n/a	0	0	0	0	0	0
VM.Standard1.1	n/a	n/a	3	0	3	0	3	0
VM.Standard1.16	n/a	n/a	0	0	0	0	0	0
VM.Standard1.2	n/a	n/a	3	0	3	0	3	0

Figure 3-27:Virtual Machine Type Limits

7. Verify that the appropriate service limits are set for your tenancy based on the VM shape chosen for the virtual machine and the region's availability domains.

To request an increase a service limits for your tenancy see [Requesting a Service Limit Increase](#).

### 3.5.9 Installing and Configuring the PBS MoM on the VM

Install the PBS MoM on the virtual machine and configure the VM per your site's environment.

Log in to the VM using the default user “opc” and the private SSH key of the user account provided during the creation of the VM. For more information see Accessing an Instance from UNIX and UNIX- Like Systems.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

1. Log in to your site's PBS Server as the user account provided during the creation of the VM.
2. SSH into the virtual machine using the default user “opc”, the private SSH key of the user account provided during the creation of the VM and the External IP assigned to the VM.

```
ssh -i PRIVATE_KEY_PATH opc@PUBLIC_IP_ADDR
```

Where PRIVATE\_KEY\_PATH is the path to the file that contains the private SSH key of the user account provided during the creation of the VM and PUBLIC\_IP\_ADDR is the public IP address of the VM.

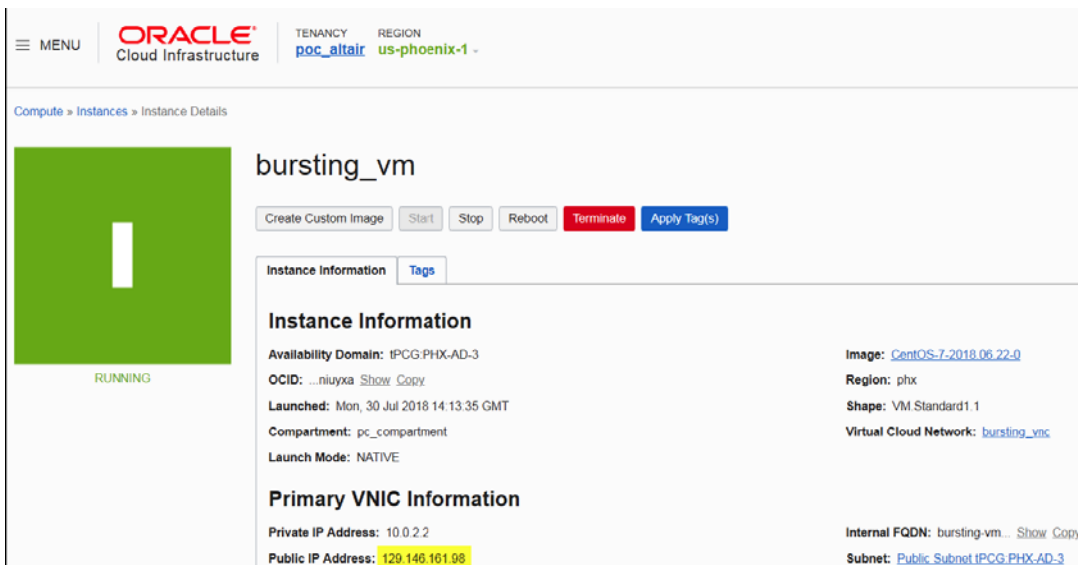

Figure 3-28: Bursting Virtual Machine

3. Enter the command:  

```
sudo -i
```
4. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
5. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
6. Install cloud-init.
7. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.5.10 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

You must have already create a virtual machine, installed the PBS MoM on the VM and configured the VM per your site's environment.

Oracle documentation can be found at Managing Custom Images.

1. Log in to the Oracle Cloud Infrastructure console.
2. Click  located in the upper left-hand corner of the web page.
3. Click Compute > Instances.

A list of virtual machines is displayed.

4. Click the name of the virtual machine created for cloud bursting.
5. Click Create Custom Image.
6. Enter the following to create a custom image:

- a. For CREATE IN COMPARTMENT, select the root compartment.
- b. For NAME, enter a name for the image.

The name can be anything meaningful to your organization, e.g., bursting\_image.

7. Click Create Custom Image.

It may take some time to create the image. Do not proceed until the image is created.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.5.11 Create an Oracle Cloud Bursting Scenario

Create an Oracle bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to the Oracle Cloud Infrastructure console. Open a second browser window and log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. Use a cloud-init script for the startup script. For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.

5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created Oracle cloud account from the list.
  - d. For Select a region, select the availability domain where the cloud bursting virtual machine is hosted.

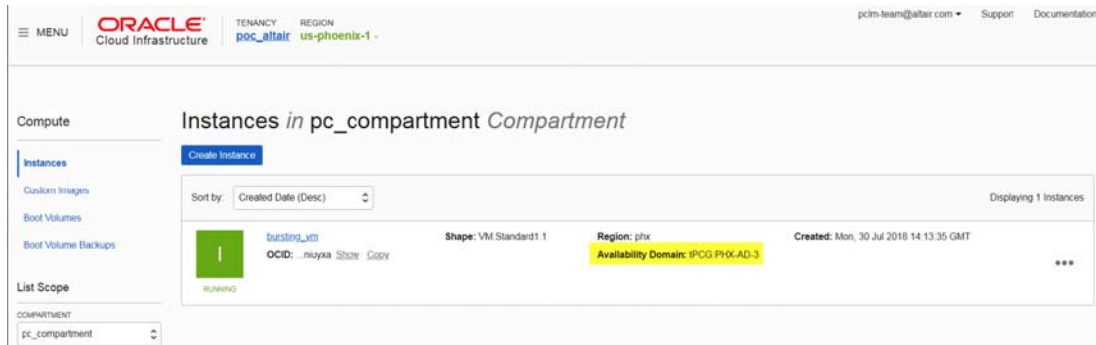

Figure 3-29: Virtual Machine Availability Domain

6. Click Next.

Enter information about the Oracle resources necessary to burst in the cloud.

7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.  
If “node” is entered, the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the Oracle Cloud Infrastructure browser window.
10. Click  located in the upper left-hand corner of the web page.
11. Click Networking > Virtual Cloud Networks.
12. Click the name of the VCN create for cloud bursting.
13. Locate the subnet associated with the availability domain where the cloud bursting virtual machine is hosted.

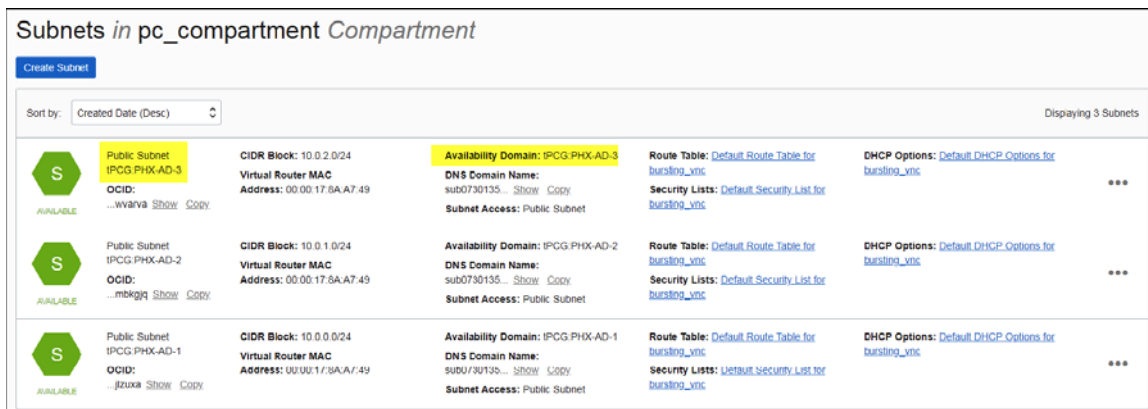

Figure 3-30: Subnet and Associated Availability Domain

14. Click Show located under the name of the subnet.

The subnet's OCID is displayed.

15. Click Copy to copy the OCID.
16. Navigate to the Cloud browser window.
17. For Subnet OCID, paste the subnet's OCID copied from Oracle.
18. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.  
It is recommended to leave this disabled.
19. Navigate to the Oracle Cloud Infrastructure browser window.
20. Click  located in the upper left-hand corner of the web page.
21. Click Compute > Custom Images. A list of custom images is displayed.
22. Locate the custom image created from the cloud bursting virtual machine.
23. Click the Show link below the name of the image to view the OCID.
24. Click Copy to copy the OCID of the image.
25. Navigate to the Cloud browser window.
26. For OS Image URI, paste the link copied from Oracle.
27. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.
28. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Log in to the PBS Server.
  - b. Copy the public SSH key for the user.  
Public key files are usually stored in `/.ssh` in the user's home directory.
  - c. Navigate to the Cloud browser window.
  - d. Click Add to add the public key.
  - e. For Public SSH keys, paste the public SSH key.
  - f. Repeat steps a through e to add additional public SSH keys.The public keys are copied to each burst node for secure connectivity.
29. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.  
It is expressed as an integer whose units are in seconds.
30. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.  
A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.  
The key-value pair must be entered as `key:value`. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).  
Once the tag is added, it will appear within its own bubble.

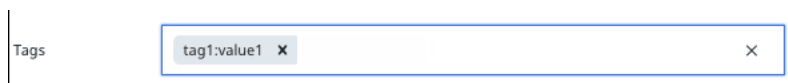

Figure 3-31:Key-Value Tag

31. Repeat the previous step to add more tags.

Figure 3-32: Additional Tags

32. Click Next.

33. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

34. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.6 Configure Orange Cloud Flexible Engine for Cloud Bursting

Create the necessary components in Orange Cloud Flexible Engine that are required for cloud bursting and then create a cloud bursting scenario.

Purchase an Orange Business Services account and use your Orange ID and password to access the Flexible Engine console. For more information visit Orange Cloud.

### 3.6.1 Create an Orange Cloud Flexible Engine User Account

Create an Orange Cloud Flexible Engine user account so that you can later create a cloud account in Cloud.

You must already have signed up for an Orange Cloud account. You should be able to log in to the Orange Cloud Customer space (<https://selfcare.cloud.orange-business.com/>) with the credentials provided to you with your Orange Cloud account. You will also be provided with a Domain name when you sign up for your Orange Cloud account.

An Orange Cloud user account must be created to add an Orange Cloud Flexible Engine account to Cloud. Once this task is complete, you should have the following information stored in a file:

- Username and password
- API password

This information is necessary to create a cloud account in Cloud.

1. Go to the Orange Cloud Customer space login page.
2. Enter your Orange Cloud credentials.

3. Click Your services.

Figure 3-33:Orange Cloud Customer Space Services

4. In the navigation bar on the top click Users
5. Click Add user.
6. Enter the following user details:
  - a. For Civility, choose Mrs or Mr
  - b. For Last name, enter the user's last name.
  - c. For First name, enter the user's first name.
  - d. For Login, enter a login name for the user.
  - e. For Email, enter the user's email address.
  - f. For Phone number, enter the user's phone number.
  - g. For Mobile phone, enter the user's mobile phone number.
  - h. For Preferred language, choose the language in which the application should be displayed.
  - i. Click next.
7. In the Roles section enter these details
  - a. For Billing, choose Visitor.
  - b. For Contracts, choose Account Manager.
  - c. For Dashboard, choose Visitor.
  - d. For Documents, choose Visitor.
  - e. For Orders, choose Visitor.
  - f. For Services, choose Visitor.
  - g. For Subscriptions, choose Visitor.
  - h. For Support, choose Visitor.
  - i. For Users. choose Manager.
  - j. For Flexible Engine Console. choose admin.
  - k. Click next.
8. In the Summary section review your choices. Click previous to edit your choices entries.
9. Click finish.

---

The new user account is created and displayed in the list of users. Emails are sent to the email address you specified. The emails will contain:

- Orange ID (Domain Name).
- Link to set Orange Password.
- Link to access Cloud Customer Space.
- Link to log in to the Flexible Engine Console.
- Link to define your API password.

10. Click the link in the email to set your Orange Password.

11. Click the link in the email to set your API Password.

12. Store the API Password to a file.

The API Password is used later to create a cloud account in Cloud.

### 3.6.2 Select a Region

Define a region in the Orange Cloud Flexible Engine console to set up the infrastructure for cloud bursting.

A region is a geographic area where resources used by your ECSs are located. ECSs in the same region can communicate with each other over an intranet, but ECSs in different regions cannot. Before setting up the infrastructure for cloud bursting, it is important to ensure that all the resources are defined in the same region. An Authorization URL is required for adding the Orange Cloud Flexible Engine cloud account in Cloud. This is based on the region selected.

1. Log in to the Orange Cloud Flexible Engine console.
2. In the navigation bar on the top, pull down the region menu and select the region for setting up your infrastructure.
3. For the Authorization URL, (IAM URL), enter the URL in the following format based on the region you chose in the Orange Cloud Flexible Engine console:

*`https://iam.<orange region>.<console link>`*

e.g. `https://iam.eu-west-0.prod-cloud-ocb.orange-business.com`

4. Store the region and Auth (IAM) URL in a file. You will use this to register the account in Cloud.

### 3.6.3 Add an Orange Cloud Flexible Engine Account

Add an existing Orange Cloud Flexible Engine account to Cloud so that you can create a cloud bursting scenario or an appliance.

You must have:

- Created an Orange Cloud Flexible Engine user account.
- Obtained the Domain name for the Orange Cloud Flexible Engine account.
- Obtained the API password for the user.
- Defined the region where you will deploy your cloud infrastructure.
- Obtained the Auth (IAM) URL based on the selected region.

This information is necessary to create a cloud account in Cloud. If you do not have this information see Create an Orange Cloud Flexible Engine User Account and Select a Region.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Cloud.

4. Click 
5. Enter the following to add a cloud account:
  - a. For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., orange\_cloudaccount.
  - b. For Auth (IAM) URL, enter the URL in the following format based on the region you chose in the Orange Cloud Flexible Engine console:  
*https://iam.<orange region>.<console link>*  
e.g. *https://iam.eu-west-0.prod-cloud-ocb.orange-business.com*
  - c. For Domain name, enter the Domain Name you used to log in to your Orange account. It is the same as your Customer ID.
  - d. For User name, enter the username of the user account you created in the Orange Cloud Customer space.
  - e. For Password, enter the API password you generated after creating the user.
6. Click Create Account.

### 3.6.4 Check Orange Cloud Flexible Engine Account Service Quota

View the your Orange Cloud Flexible Engine resource usage and limits from the console.

Quotas are used to limit the number of resources available to users. It is important to ensure you are not exceeding your quota while setting up the resources for cloud bursting. If the existing resource quota cannot meet your service requirements, you can submit a work order to increase your quota. Once your application is approved, Orange Cloud Flexible Engine will update your resource quota accordingly and send you a notification.

1. Log in to the Orange Cloud Flexible Engine console.
2. In the navigation bar on the top right hand side, click   
Information about resources usage and availability is displayed.

### 3.6.5 Create a Virtual Private Cloud

Create a Virtual Private Cloud (VPC) so that you can perform cloud bursting.

Orange Cloud Flexible Engine documentation for VPC can be found at: [Virtual Private Cloud Documentation](#)

1. Log in to the Orange Cloud Flexible Engine console.
2. In the top navigation bar select the region where you wish to deploy your cloud infrastructure.
3. From the Network section click Virtual Private Cloud.
4. Click + Create VPC.
5. In the Basic Information section:
  - a. For Region, ensure the VPC is the same region as the other resources.
  - a. For Name, enter a name for the VPC.
  - a. For CIDR Block, enter CIDR values for the VPC.

6. In the Subnet Settings section:
  - a. For the Subnet Settings choose the AZ (Availability Zone) as the same as the region.
  - b. For Subnet Name, enter a name to match the VPC Name.
  - c. Enter CIDR Block for Subnet.
  - d. For Advanced Settings, click Default.
7. Review the Configuration information.
8. Click Create Now.
9. Once the VPC is created, click the Back to VPC List.
10. Click Security Group in the left hand side menu.
11. Click + Create Security Group.
12. For Name, enter a name for the Security Group.
13. For Description, enter a suitable Description.
14. Click OK
15. By default, the Outbound and Inbound traffic over IPv4 is open. You can add firewall rules to this security group if required.

### 3.6.6 Creating a Virtual Machine

Create an Elastic Cloud Server (ECS) using a public image provided by Orange Cloud Flexible Engine for cloud bursting.

You must have already created a Virtual Private Network with a subnet and assigned a Security Group. If you do not have this information, see [Create a Virtual Private Cloud](#)

1. Log in to the Orange Cloud Flexible Engine console.
2. In the Computing section and click Elastic Cloud Server.
3. From the menu on the left hand side click Key Pair.
4. Click + Create Key Pair.
5. Enter a Name for the Key Pair.
6. Click OK.
7. Save the Key Pair (.pem) file to your local disk in a secure location. The information in this .pem file is used later to SSH into the VM.
8. Click OK to confirm that you have downloaded the Key Pair file.
9. From the menu on the left hand side, click Elastic Cloud Server.
10. Click + Create ECS.
11. For Region, click the region you selected for setting up the infrastructure.
12. For AZ (Availability Zone), select the AZ related to the region.
13. In the Specifications section:
  - a. For ECS type, click one of the flavor names. Orange Cloud Flexible Engine provides a set of predefined ECS types for specific requirements. Click a flavor name to get the list of available configurations.
  - b. Review the specifications you have selected.

14. In the Image section:
  - a. Click Public image.
  - b. From the drop down menu select CentOS
  - c. From the version drop down menu select Select OBS\_U\_CentOS\_7.2(40GB)
15. In the Disk section select the defaults.
16. In the VPC section:
  - a. For VPC, select the VPC you created from the drop down menu.
  - a. For NIC, choose the default primary NIC.
  - b. For Security Group, select the Security Group you created for the VPC.
  - c. For EIP, click Automatically assign
  - d. For Bandwidth, specify it as 5 Mbit/s.
17. For Login Mode, select the Key Pair you generated earlier from the drop down menu.
18. For Auto Recovery, click Enable.
19. For Advanced Settings, click Do not configure.
20. For ECS Name, enter a name.
21. For Quantity, specify 1.
22. Review the Current Configuration.
23. Click Create Now.
24. Review the Specifications.
25. Click Submit.

The ECS (Virtual Machine) is created and displayed in the list of ECS.

### 3.6.7 Installing and Configuring the PBS MoM on the VM

Install the PBS MoM on the virtual machine and configure the VM per your site's environment.

Log in to the VM using the default user "cloud" and the .pem generated during the creation of the VM. For more information about logging into the Linux ECS, refer to the Elastic Cloud Server User Guide.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

1. Log in to your site's PBS Server.
2. Log in to the Flexible Engine console.
3. In the Computing section, click Elastic Cloud Server.
4. In the search box above the upper right corner of the ECS list, enter the ECS name, IP address, or ID, and click the search icon.
5. Click the name of the target ECS.
6. The page providing details about the ECS is displayed.

7. Copy the Public IP address (External IP) of the ECS.
8. SSH into the VM using the default user “cloud”, the .pem file you generated when creating the VM and the External IP assigned to the VM.

```
ssh -i /path/my-key-pair.pem cloud@IPV4PublicIP
```

where /path/my-key-pair.pem is the path to the .pem file downloaded while creating the virtual machine and IPV4PublicIP is the public IP address of the virtual machine.

9. Enter the command:

```
sudo -i
```

10. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
11. Save the file.
12. Configure the VM for your site’s environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
13. Install cloud-init.
14. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.6.8 Create an OS Image

Create an image of the virtual machine configured per your site’s requirements.

You must have already created a ECS (VM), installed the PBS MoM on the VM and configured it per your site’s environment.

Orange Cloud Flexible Engine documentation can be found at [Creating a Linux Private Image Using an ECS](#). Before creating the Image from the ECS, you must have.

- A Linux ECS in the Stopped state.
  - Configured DHCP for the NICs of the ECS
  - Configured Network attributes of the ECS
  - Detached Data Disks from the ECS
1. Log in to the Flexible Engine console.
  2. In the Computing section, click Image Management Service.
  3. On the Image Management Service page, click + Create Private Image.
  4. In the Image Type and Source section, .
    - a. For Type, click System disk image
    - b. For Source, click ECS
    - c. Select the target ECS from the ECS list.
  5. Set the required information, such as Name and Description.
  6. Click Create Now.
  7. Confirm the parameters and click Submit.
  8. Switch back to the Image Management Service page to view the image status.

The time required for creating an image varies depending on the image file size. Generally, it takes about 20 minutes to create an image. The image is successfully created when its image status changes to Normal.

Do not perform any operation on the selected ECS or its associated resources during image creation.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.6.9 Create Orange Cloud Cloud Bursting Scenario

Create an Orange Cloud Flexible Engine bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to the Orange Cloud Flexible Engine console. Open a second browser window and Log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. Use a cloud-init script for the startup script. For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created Orange Cloud Flexible Engine account from the list.
  - d. For Select a region, select the availability domain where the cloud bursting virtual machine is hosted.
6. Click Next.
7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.  
If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the Orange Cloud Flexible Engine console browser window.
10. Click Service List in the menu bar.

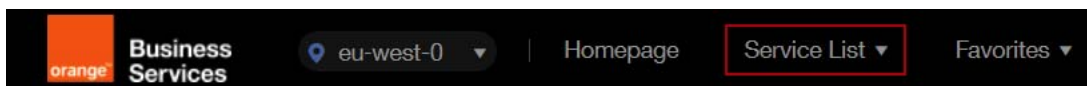

Figure 3-34: Orange Cloud Flexible Engine Console

11. Under Network, click Virtual Private Cloud.
12. Click Virtual Private Cloud from the menu located on the left-hand side of the web page.
13. Click the name of the VPC you created for cloud bursting.
14. Click the name of the Subnet for the VPC.
15. Copy the Subnet ID.
16. Navigate to the Cloud browser window.
17. For Subnet ID, paste the subnet’s ID copied from the Orange Cloud Flexible Engine console.
18. In the Orange Cloud Flexible Engine console browser window click Security Group from the left hand side menu.
19. Click the name of the Security Group you created for the VPC.

20. Copy the ID of the Security Group.
21. Navigate to the Cloud browser window.
22. For Security Group ID, paste the security group's ID you copied from the Orange Cloud Flexible Engine console.
23. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.
24. It is recommended to leave this disabled.
25. Navigate to the Orange Cloud Flexible Engine console browser window.
26. Click Service List in the menu bar.
27. Under Computing, click Image Management Service.
28. Click the Private Images tab.
29. Click the name of the VM image you created for cloud bursting.
30. Copy the ID of the image.
31. Navigate to the Cloud browser window.
32. For OS Image URI, paste the image ID you copied from the Orange Cloud Flexible Engine console.
33. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.
34. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Log in to the PBS Server.
  - b. Copy the public SSH key for the user.  
Public key files are usually stored in `/.ssh` in the user's home directory.
  - c. Navigate to the Cloud browser window.
  - d. Click Add to add the public key.
  - e. For Public SSH keys, paste the public SSH key.
  - f. Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.
35. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.  
It is expressed as an integer whose units are in seconds.
36. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as `key:value`. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

Figure 3-35:Key-Value Tag

37. Repeat the previous step to add more tags.

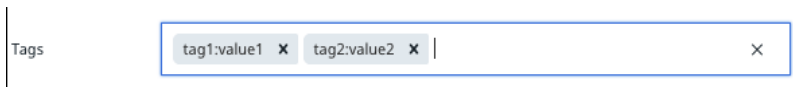

Figure 3-36:Additional Tags

38. Click Next.
39. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

40. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.7 Configure HUAWEI Cloud for Cloud Bursting

Create the necessary components in HUAWEI Cloud that are required for cloud bursting and then create a cloud bursting scenario.

Before you can begin creating the components necessary for cloud bursting, you must create and activate an HUAWEI Cloud account.

### 3.7.1 Obtain the HUAWEI Cloud Administrator Credentials

Get the credentials for the HUAWEI Cloud administrative user account so that you can later use this information to create a cloud account in Cloud.

You must already have signed up for an HUAWEI Cloud account.

When subscribing to HUAWEI Cloud, an administrative user account that has permissions for all system operations is automatically created. Use this user account to add an HUAWEI Cloud account to Cloud. Reset the password for this account when the password is unknown.

Alternatively, you can create a new user and give the user administrative privileges by setting its User Group to “admin”.

1. Log in to the HUAWEI Cloud Console.
2. Click Service List.

Figure 3-37:HUAWEI Cloud Console

3. Under Management & Deployment, click Identity and Access Management.
4. Click Users from the menu located on the left-hand side of the web page. A list of users is displayed.
5. Click the down-arrow located next to a username to display the user’s details.

The user account listed as an “admin” is the account to use to create the cloud account in Cloud.

<b>Basic Information</b>			
Username	admin	Status	Enabled
User ID	admin	Mobile Number	+86 186****13
Email	y**g@altair.com.cn	Login Authentication Method	Disable
Description	Enterprise administrator		
<b>User Groups</b>		<b>User Logs</b>	
User Group	Description	Created	08/09/2017 03:40:50 GMT-04:00
admin	User group that has permissions for all system operations.	Last Successful Login	10/29/2018 16:21:53 GMT-04:00
		Last Password Change	03/05/2018 21:51:44 GMT-04:00
		Last Access Key Created	-

Figure 3-38:User Details

- If you do not know the password for the administrative user account, click Set Credentials.

Username	Description	Status	Last Login	Created	Operation
admin	-	Enabled	10/29/2018 16:23:56 GMT-04:00	10/29/2018 16:23:56 GMT-04:00	<a href="#">Set Credentials</a> <a href="#">Delete</a> <a href="#">Modify</a>
admin	Enterprise administrator	Enabled	10/29/2018 16:21:53 GMT-04:00	08/09/2017 03:40:50 GMT-04:00	<a href="#">Set Credentials</a> <a href="#">Delete</a> <a href="#">Modify</a>

Figure 3-39:Set Password

- Enable Set manually.
- For Password, enter a password for the user account.
- For Confirm Password, enter the password a second time.
- Click OK.

You may have to confirm the password change either by email or by a SMS text.

### 3.7.2 Add an HUAWEI Cloud Account

Add an existing HUAWEI Cloud account to Cloud so that you can create a cloud bursting scenario.

- Log in to Cloud.
- Click the Cloud tab.
- Under Infrastructure, click Cloud.
- Click .
- Enter the following to add a cloud account:
  - For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., huawei\_cloudaccount.
  - For Auth (IAM) URL, enter https://iam.ap-southeast-1.myhwclouds.com.
  - For Domain name, enter the Domain Name provided when your subscription to HUAWEI Cloud was created.  
If you do not know your Domain name, contact HUAWEI Cloud support.
  - For Username, enter a username that is an HUAWEI Cloud administrator.
  - For Password, enter the password for the HUAWEI Cloud administrator.
- Click Create Account.

### 3.7.3 Check HUAWEI Cloud Account Service Quotas

View your OTC account resource usage and limits.

Quotas are used to limit the number of resources available to users. It is important to ensure you are not exceeding your quota while setting up the resources for cloud bursting. If the existing resource quota cannot meet your service requirements, you can submit a work order to increase your quota. Once your application is approved, HUAWEI Cloud will update your resource quota accordingly and send you a notification.

1. Log in to the HUAWEI Cloud console.
2. Click Resources > My Quota.

Information about resources usage and availability is displayed.

### 3.7.4 Create a Virtual Private Cloud

Create a Virtual Private Cloud (VPC) so that you can perform cloud bursting.

HUAWEI Cloud documentation for creating a VPC can be found at: [Creating a VPC and Regions and AZs](#).

1. Log in to the HUAWEI Cloud Console.
2. Click Service List in the menu bar.
3. Under Network, click Virtual Private Cloud.
4. Click + Create VPC.
5. In the Basic Information section:
  - a. For Region, select a region.

Regions are geographic areas isolated from each other. Resources are region-specific and cannot be used across regions through internal network connections. For low network latency and quick resource access, select the nearest region.
  - b. For Name, enter a name for the VPC.
  - c. For CIDR Block, enter an address range for the network using CIDR notation.
6. In the Subnet Settings section:
  - a. For the Subnet Settings choose the AZ (Availability Zone).

An Availability Zone is a physical location where resources use independent power supplies and networks. AZs are physically isolated and AZs in the same VPC are interconnected through an internal network.
  - b. For Subnet Name, enter a name for the subnet.
  - c. For CIDR, enter an address range for the subnet using CIDR notation.
  - d. For Advanced Settings, click Default.
7. Click Create Now.
8. Click Back to VPC List.
9. Click Security Group in the left hand side menu.
10. Click + Create Security Group.
11. For Name, enter a name for the security group.
12. For Description, enter a suitable description.
13. Click OK.
14. By default, the Outbound and Inbound traffic over IPv4 is open. You can add firewall rules to this security group if required.

---

### 3.7.5 Creating a Virtual Machine

Create an Elastic Cloud Server (ECS) using a public image provided by HUAWEI Cloud for cloud bursting.

You must have already created a Virtual Private Network with a subnet and assigned a Security Group. If you do not have this information, see [Create a Virtual Private Cloud](#).

HUAWEI Cloud documentation for creating an ECS (virtual machine) can be found at [Purchase an ECS](#).

1. Log in to the HUAWEI Cloud Console.
2. Click Service List in the menu bar.
3. Under Computing, click Elastic Cloud Server.
4. Click Key Pair from the menu located on the left-hand side of the web page.
5. Click + Create Key Pair.
6. For Name, enter a name for the key pair.
7. Click OK.
8. Save the key pair (.pem) file to your local disk in a secure location. The information in this .pem file is used later to SSH into the VM.
9. Click OK to confirm that you have downloaded the key pair file.
10. Click Elastic Cloud Server from the menu located on the left-hand side of the web page.
11. Click Buy ECS.
12. For Billing Mode, click Pay-per-use.
13. For Region, select the same region that was chosen for the previously created VPC.
14. For AZ (Availability Zone), select the same AZ that was chosen for the previously created VPC.
15. In the Type section:
  - a. Choose an ECS type category:
    - General computing
    - General computing-plus
    - Memory-optimized
    - Large-memory
    - High-performance computing
    - Disk-intensive
  - b. For ECS type, click one of the flavor based on the needs of your site.
16. In the Image section:
  - a. Click Public image.
  - b. For Select an OS, select CentOS.
  - c. For Select an OS version, select CentOS 7.2 64bit(40GB).
17. In the Disk section, select your system disk requirements.

18. In the VPC section:
  - a. For VPC, select the VPC you created for cloud bursting. The NIC information is automatically populated.
  - b. For Security Group, select the security group you created for cloud bursting.
  - c. For EIP, click Automatically assign
  - d. For Bandwidth, specify it as 5 Mbit/s.
19. For Login Mode, select Key Pair.
20. For Key Pair, select the key pair file you generated earlier.
21. For Advanced Settings, click Not required.
22. For ECS Name, enter a name for the virtual machine.
23. For Quantity, specify 1.
24. Click Next.
25. Review the specifications.
26. Enable the I have read and agree to the Huawei Image Disclaimer checkbox.
27. Click Submit Application.
28. Click Back to ECS List.

It may take some time to create the virtual machine. Once the ECS is created it is displayed in the ECS list.

### 3.7.6 Installing and Configuring the PBS MoM on the VM

Install the PBS MoM on the virtual machine and configure the VM per your site's environment.

Log in to the VM using the default user “root” and the .pem generated during the creation of the VM.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

1. Log in to the HUAWEI Cloud console.
2. Click Service List in the menu bar.
3. Under Computing, click Elastic Cloud Server.
4. Copy the Public IP address (External IP) of the ECS.

<input type="checkbox"/>	Name/ID	AZ	Status	Type/Image	IP Address	Billing Mode	Operation
<input type="checkbox"/>	cloud-burst-vm b01fe2b1-5407-4246-b690-8c37930a...	AZ1	Running	1 vCPUs   1 GB   s3.small.1 CentOS 7.2 64bit	159.138.22.245 (EIP) 5 Mbit/s 10.0.0.123 (Private IP)	Pay-per-use	Remote Login More ▾
<input type="checkbox"/>	huawei-head 4f749087-8bb3-4cbf-b835-f1fdb4113...	AZ1	Running	8 vCPUs   32 GB   s3.2xlarge.4 CentOS 7.5 64bit	159.138.23.124 (EIP) 12 Mbit/s 10.0.6.94 (Private IP)	Pay-per-use	Remote Login More ▾

Figure 3-40: VM IP Address

5. Log in to your site's PBS Server.
6. SSH into the VM using the default user “root”, the .pem file you generated when creating the VM and the External IP assigned to the VM.

```
sh -i /path/my-key-pair.pem root@IPV4PublicIP
```

---

where `/path/my-key-pair.pem` is the path to the `.pem` file downloaded while creating the virtual machine and `IPV4PublicIP` is the public IP address of the virtual machine.

7. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
8. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
9. Install `cloud-init`.
10. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.7.7 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

You must have already created a ECS (virtual machine), installed the PBS MoM on the ECS and configured it per your site's environment.

HUAWEI Cloud documentation can be found at [Creating a Linux Private Image](#).

1. Log in to the HUAWEI Cloud console.
2. Click Service List in the menu bar.
3. Under Computing, click Image Management Service.
4. Click + Create Image.
5. For Region, select the same region that was chosen for the previously created VPC and ECS.
6. In the Image Type and Source section, .
  - a. For Type, click System disk image.
  - b. For Source, click ECS.
  - c. Select the virtual machine created for cloud bursting.
  - d. For Name, enter a name for the virtual machine.
7. Click Next.
8. Review the specifications.
9. Enable the I have read and agree to the Statement of Commitment to Image Creation and Huawei Image Disclaimer checkbox.
10. Click Submit.
11. Click Back to Image List.

The time required for creating an image varies depending on the image file size. Generally, it takes about 20 minutes to create an image. The image is successfully created when its image status changes to Normal.

Do not perform any operation on the selected ECS or its associated resources during image creation.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.7.8 Create a HUAWEI Cloud Bursting Scenario

Create an HUAWEI Cloud bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to the HUAWEI Cloud console. Open a second browser window and log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. Use a cloud-init script for the startup script. For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created HUAWEI Cloud account from the list.
  - d. For Select a region, select the same region that was chosen for the previously created VM and VPC.
6. Click Next.

Enter information about the HUAWEI Cloud resources necessary to burst in the cloud.

7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com
8. For Hostname prefix, enter a prefix for the names of the burst nodes.

If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the HUAWEI Cloud console browser window.
10. Click Service List in the menu bar.
11. Under Network, click Virtual Private Cloud.
12. Click Virtual Private Cloud from the menu located on the left-hand side of the web page.
13. Click the name of the VPC you created for cloud bursting.
14. Click the name of the VPC’s subnet.
15. Copy the Subnet ID.
16. Navigate to the Cloud browser window.
17. For Subnet ID, paste the subnet’s ID copied from HUAWEI Cloud console.
18. In the HUAWEI Cloud console browser window click Security Group from the menu located on the left-hand side of the web page.
19. Click the name of the security group you created for the VPC.
20. Copy the ID of the security group.
21. Navigate to the Cloud browser window.
22. For Security Group, paste the security group’s ID you copied from the HUAWEI Cloud console.
23. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet.

It is recommended to leave this disabled.
24. Navigate to the HUAWEI Cloud console browser window.
25. Click Service List in the menu bar.

26. Under Computing, click Image Management Service.
27. Click the Private Images tab.
28. Click the name of the VM image you created for cloud bursting.
29. Copy the ID of the image.
30. Navigate to the Cloud browser window.
31. For OS Image URI, paste the image ID you copied from the HUAWEI Cloud console.
32. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.
33. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Log in to the PBS Server.
  - b. Copy the public SSH key for the user.  
Public key files are usually stored in `/.ssh` in the user's home directory.
  - c. Navigate to the Cloud browser window.
  - d. Click Add to add the public key.
  - e. For Public SSH keys, paste the public SSH key.
  - f. Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.

34. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst.

It is expressed as an integer whose units are in seconds.

35. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as `key:value`. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

Figure 3-41:Key-Value Tag

36. Repeat the previous step to add more tags.

Figure 3-42:Additional Tags

37. Click Next.
38. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

---

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

39. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.8 Configure Open Telekom Cloud for Cloud Bursting

Create the necessary components in Open Telekom Cloud (OTC) that are required for cloud bursting and then create a cloud bursting scenario.

Before you can begin creating the components necessary for cloud bursting, you must create and activate an OTC Cloud account.

### 3.8.1 Obtain the OTC Administrator Credentials

Get the credentials for the OTC administrative user account so that you can later use this information to create a cloud account in Cloud.

You must already have signed up for an OTC account.

When subscribing to OTC, an administrative user account that has permissions for all system operations is automatically created. Use this user account to add an OTC cloud account to Cloud. Reset the password for this account when the password is unknown.

Alternatively, you can create a new user and give the user administrative privileges by setting its User Group to “admin”.

1. Log in to the OTC Console.
2. Click Service List in the menu bar.
3. Under Management & Deployment, click Identity and Access Management.
4. Click Users from the menu located on the left-hand side of the web page. A list of users is displayed.
5. Click the down-arrow located next to a username to display the user’s details.

The user account listed as an “admin” is the account to use to create the cloud account in Cloud.

**Basic Information**

Username	15020293 OTC-EU-DE-00000000001000030142	Status	Enabled
User ID	15020293 OTC-EU-DE-00000000001000030142	Mobile Number	--
Email	j***e@altair.com	Verify Login by SMS Message	This function cannot be enabled. Bind a mobile number and email address.
Description	User: 15020293 OTC00000000001000030142, ICU Id: 15020293		

**User Groups**

User Group	Description
admin	User group that has permissions for all system operations.

**User Logs**

Created	2018-04-25 08:31:47 GMT-04:00
Last Successful Login	2018-05-14 06:10:00 GMT-04:00
Last Password Change	--
Last Access Key Created	--

Figure 3-43:User Details

- If you do not know the password for the admin user account, click Set Credentials

Username	Description	Status	Last Login	Created	Operation
15020293 OTC-EU-...	User: 15020293 OTC0000000000100...	Enabled	2018-05-14 06:10:00 GMT-04:00	2018-04-25 08:31:47 GMT-04:00	Set Credentials Delete Modify
15030774 OTC-EU-...	User: 15030774 OTC-EU-DE-000000...	Enabled	2018-10-29 07:06:21 GMT-04:00	2018-05-14 06:20:45 GMT-04:00	Set Credentials Delete Modify

Figure 3-44:Set Password

- Enable Set manually.
- For Password, enter a password for the user account.
- For Confirm Password, enter the password a second time.
- Click OK.

You may have to confirm the password change either by email or by a SMS text.

## 3.8.2 Add an OTC Account

Add an existing OTC Cloud account to Cloud so that you can create a cloud bursting scenario.

- Log in to Cloud.
- Click the Cloud tab.
- Under Infrastructure, click Cloud.
- Click 
- Enter the following to add a cloud account:
  - For Account name, enter any name for the cloud account.  
The name can be anything meaningful to your organization, e.g., orange\_cloudaccount.
  - For Auth (IAM) URL, enter: `https://iam.eu-de.otc.t-systems.com/v3`.
  - For Domain name, enter the OTC Domain Name you used to log in to the OTC console.
  - For Username, enter a username that is an OTC administrator.
  - For Password, enter the password for the OTC administrator.
- Click Create Account.

### 3.8.3 Check OTC Account Service Quotas

View your OTC account resource usage and limits.

Quotas are used to limit the number of resources available to users. It is important to ensure you are not exceeding your quota while setting up the resources for cloud bursting. If the existing resource quota cannot meet your service requirements, you can submit a work order to increase your quota. Once your application is approved, OTC will update your resource quota accordingly and send you a notification.

1. Log in to the OTC Console.
2. Click the three vertical bars in the menu bar:

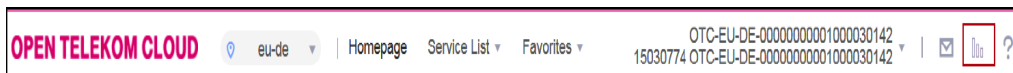

Figure 3-45: Viewing Quotas

You can see resource usage and availability:

Service Quota <small>Quotas are used to prevent the overuse of resources. If you need additional resources, you can apply to increase your quota.</small>				Increase Quota
Service	Resource Type	Used Quota	Total Quota	
Elastic Cloud Server	ECS	0	100	
	vCPU	0	400	
	Memory (MB)	0	2,048,000	
Auto Scaling	AS group	0	25	
	AS configuration	0	100	
	ess_bandwidth_scaling_policy	0	50	
Image Management Service	Image	0	100	
Elastic Volume Service	Disk	0	50	
	Disk capacity (GB)	0	12,500	
	Snapshots	0	3,000	
Volume Backup Service	Backup	0	1,800	
Virtual Private Cloud	VPC	2	10	
	Subnet	4	100	
	Security group	4	100	

Figure 3-46: Resource quotas and availability

### 3.8.4 Create a Virtual Private Cloud

Create a Virtual Private Cloud (VPC) so that you can perform cloud bursting.

OTC documentation for creating a VPC can be found at: [Creating a VPC and Regions](#).

1. Log in to the OTC Console.
2. Click Service List.
3. Under Network, click Virtual Private Cloud.
4. Click + Create VPC.

5. In the Basic Information section:

- a. For Region, select a region.

Figure 3-47:Regions

A region is a geographical areas and can comprise one or more availability zones (AZs). A region is completely isolated from other regions. Only AZs in the same region can communicate with one another through an internal network.

- b. For Name, enter a name for the VPC.
  - c. For CIDR Block, enter an address range for the network using CIDR notation.
6. In the Subnet Settings section:
- a. For Subnet Name, enter a name for the subnet.
  - b. For CIDR, enter an address range for the subnet using CIDR notation.
  - c. For Advanced Settings, click Default.
7. Click Create Now.
8. Click Back to VPC List.
9. Click Security Group in the left hand side menu.
10. Click + Create Security Group.
11. For Name, enter a name for the security group.
12. For Description, enter a suitable description.
13. Click OK.
- The security group rules are displayed.
14. Click the Inbound tab.
15. Click Add Rule.
- a. For Protocol/Application, select TCP.
  - b. For Port, enter 22.
  - c. For Source, select IP Address. and enter 0.0.0.0/0.
  - d. Click OK.

### 3.8.5 Creating a Virtual Machine

Create an Elastic Cloud Server (ECS) using a public image provided by OTC for cloud bursting.

You must have already created a Virtual Private Network with a subnet and assigned a Security Group. If you do not have this information, see Create a Virtual Private Cloud.

OTC documentation for creating an ECS (virtual machine) can be found at Create an ECS.

1. Log in to the OTC Console.
1. Click Service List in the menu bar.
2. Under Computing, click Elastic Cloud Server.
3. Click Key Pair from the menu located on the left-hand side of the web page.

- 
4. Click + Create Key Pair.
  5. For Name, enter a name for the key pair.
  6. Click OK.
  7. Save the key pair (.pem) file to your local disk in a secure location. The information in this .pem file is used later to SSH into the VM.
  8. Click OK to confirm that you have downloaded the key pair file.
  9. Click Elastic Cloud Server from the menu located on the left-hand side of the web page.
  10. Click Create ECS.
  11. For Region, select the same region that was chosen for the previously created VPC.
  12. For AZ (Availability Zone), select an availability zone.
  13. In the Specifications section:
    - a. Choose an ECS type category:
      - General-purpose
      - Dedicated general-purpose
      - Memory-optimized
      - Large-memory
      - High-performance
      - Disk-intensive
      - GPU-accelerated
    - b. For ECS type, choose one of the flavors based on the needs of your site.
  14. In the Image section:
    - a. Click Public image.
    - b. Select CentOS as the operating system.
    - c. Select Standard\_CentOS7\_latest(4GB) for the OS version..
  15. In the Disk section, select your system disk requirements.
  16. In the VPC section:
    - a. For VPC, select the VPC you created for cloud bursting. The NIC information is automatically populated.
    - b. For Security Group, select the security group you created for cloud bursting.
    - c. For EIP, click Automatically assign
    - d. For Bandwidth, specify it as 5 Mbit/s.
  17. For Log in Mode, select Key Pair.
  18. For Key Pair, select the key pair file you generated earlier.
  19. For Advanced Settings, click Do not configure.
  20. For ECS Name, enter a name for the virtual machine.
  21. For Quantity, specify 1.
  22. Click Create Now.
  23. Review the specifications.

24. Click Submit.
25. Click Back to ECS List.

It may take some time to create the virtual machine. Once the ECS is created it is displayed in the ECS list.

### 3.8.6 Installing and Configuring the PBS MoM on the VM

Install the PBS MoM on the virtual machine and configure the VM per your site's environment.

Log in to the VM using the default user “root” and the .pem generated during the creation of the VM.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. A service specifically designed for cloud instance initialization is cloud-init and is utilized by Cloud when booting cloud nodes, therefore it must be installed on the VM. For more information about installing cloud-init, refer to the Cloudinit Documentation.

1. Log in to the OTC Console.
2. Click Service List in the menu bar.
3. Under Computing, click Elastic Cloud Server.
4. Copy the Public IP address (External IP) of the ECS.

Name/ID	AZ	Status	Specifications/Image	Private IP Address	EIP	Operation
<input type="checkbox"/> a10e9eeb-2ba7-4c97-b886-19c5...	eu-de-02	Running	1 vCPUs   1 GB   s2 me... Standard_CentOS_7_lat...	10.0.0.221	160.44.198.17	Remote Login More ▾

Figure 3-48: VM IP Address

5. Log in to your site's PBS Server.
6. SSH into the VM using the default user “root”, the .pem file you generated when creating the VM and the External IP assigned to the VM.
 

```
ssh -i /path/my-key-pair.pem root@IPV4PublicIP
```

where /path/my-key-pair.pem is the path to the .pem file downloaded while creating the virtual machine and IPV4PublicIP is the public IP address of the virtual machine.
7. Using the PBS Professional Installation and Upgrade Guide, install and configure the PBS MOM.
8. Configure the VM for your site's environment such as mounting file systems, connecting it to the authentication service, installing any applications, etc.
9. Install cloud-init.
10. Connect the VM to your PBS server and submit a job to ensure it is working as expected.

### 3.8.7 Create an OS Image

Create an image of the virtual machine configured per your site's requirements.

You must have already created a ECS (virtual machine), installed the PBS MoM on the ECS and configured it per your site's environment.

OTC documentation can be found at Creating a Linux Private Image.

1. Log in to the OTC Console.
2. Click Service List in the menu bar.

3. Under Computing, click Image Management Service.
4. Click + Create System Disk Image.
  - a. For Region, select the same region that was chosen for the previously created VPC and ECS.
  - b. For Source, click Server.
  - c. For Server Type, click ECS.
  - d. For ECS, select the virtual machine created for cloud bursting.
  - e. If the virtual machine is not stopped, stop it.
  - f. Click OK when prompted to verify that certain operations have been performed on the ECS. You do not need to configure or optimize the ECS.
  - g. For Name, enter a name for the virtual machine.
5. Click Create Now.
6. Review the specifications.
7. Click Submit.
8. Click Back to Image List.

The time required for creating an image varies depending on the image file size. Generally, it takes about 20 minutes to create an image. The image is successfully created when its image status changes to Normal.

Do not perform any operation on the selected ECS or its associated resources during image creation.

You can now delete the virtual machine so that you are no longer charged for it.

### 3.8.8 Create an OTC Cloud Bursting Scenario

Create an OTC bursting scenario so that PBS execution nodes can be burst in the cloud.

Open a browser window and log in to the OTC Console. Open a second browser window and log in to Cloud.

A startup script is provided during the creation of the bursting scenario. This script is ran after a cloud node is burst and is used to set up the system environment so that nodes burst in the cloud can communicate with the PBS Server. Use a cloud-init script for the startup script. For more information about writing cloud-init scripts, refer to the Cloudinit Documentation and Cloud Bursting Startup Script.

1. Navigate to the Cloud browser window.
2. Click Cloud.
3. Under Infrastructure, click Bursting.
4. Click Add Bursting Scenario.
5. Enter information about the bursting scenario such as name, cloud provider, cloud account, and geographic location.
  - a. For Name, enter a name for the cloud bursting scenario.
  - b. For Description, enter a description.
  - c. For Cloud Account, choose a previously created OTC cloud account from the list.
  - d. For Select a region, select the same region that was chosen for the previously created VM and VPC.
6. Click Next.

Enter information about the OTC resources necessary to burst in the cloud.

7. For Domain name, provide the domain name of your organization for the cloud bursting network. altair.com, burst.altair.com

8. For Hostname prefix, enter a prefix for the names of the burst nodes.  
If “node” is entered , the cloud bursting nodes will be available to PBS Professional as node1, node2, node3, etc.
9. Navigate to the OTC console browser window.
10. Click Service List in the menu bar.
11. Under Network, click Virtual Private Cloud.
12. Click Virtual Private Cloud from the menu located on the left-hand side of the web page.
13. Click the name of the VPC you created for cloud bursting.
14. Click the name of the VPC’s subnet.
15. Copy the Subnet ID.
16. Navigate to the Cloud browser window.
17. For Subnet ID, paste the subnet’s ID copied from the OTC console.
18. In the OTC console browser window, click Security Group from the menu located on the left- hand side of the web page.
19. Click the name of the security group you created for the VPC.
20. Copy the ID of the security group.
21. Navigate to the Cloud browser window.
22. For Security Group, paste the security group’s ID you copied from the OTC console.
23. Enable the Add public IP to VMs if you need to connect to the cloud bursting nodes from the internet. It is recommended to leave this disabled.
24. Navigate to the OTC console browser window.
25. Click Service List in the menu bar.
26. Under Computing, click Image Management Service.
27. Click the Private Images tab.
28. Click the name of the VM image you created for cloud bursting.
29. Copy the Image ID of the image.
30. Navigate to the Cloud browser window.
31. For OS Image URI, paste the image ID you copied from the OTC console.
32. For Cloud-init script, click Browse, browse for the startup script file and add it. This script will run after a cloud node is burst.
33. Add public SSH keys for any users that you want to have access to the burst nodes:
  - a. Log in to the PBS Server.
  - b. Copy the public SSH key for the user.
  - c. Public key files are usually stored in /.ssh in the user’s home directory.
  - d. Navigate to the Cloud browser window.
  - e. Click Add to add the public key.
  - f. For Public SSH keys, paste the public SSH key.
  - g. Repeat steps a through e to add additional public SSH keys.

The public keys are copied to each burst node for secure connectivity.

34. For Idle before unburst, enter the minimum time that a cloud node can be idle before it is unburst. It is expressed as an integer whose units are in seconds.
35. For Tags, enter a key-value pair to add a label to the cloud node and press ENTER.

A tag is a label that is assigned to a cloud node. Tags enable cloud nodes to be categorized in different ways, for example, by purpose, owner, or environment.

The key-value pair must be entered as key:value. The key must be less than 36 characters and the value must be less than 43 characters. The length of both the key + value should be less than 80 characters. Valid values are alphanumeric, dash (-) and an underscore (\_).

Once the tag is added, it will appear within its own bubble.

Figure 3-49:Key-Value Tag

36. Repeat the previous step to add more tags.

Figure 3-50:Additional Tags

37. Click Next.
38. Select the instance types to enable for the bursting scenario by clicking the Enabled checkbox located to the far right of the instance type name

If an attempt is made to burst nodes with a disabled instance type, the node is not burst and the below message is displayed in the PBS Server logs (if bursting through PBS), the Cloud logs and through the Cloud component user interface.

TYPE is not enabled

Where TYPE is the instance type used when attempting to burst the node.

39. Click Instantiate scenario.

Once the scenario created, it is recommended to Add a Token and Add Quotas and Alerts. When adding a token, an API key is generated that is required for bursting. Quotas define bursting limits such as the maximum number of cloud nodes to burst.

## 3.9 AWS Spot Pricing

Use AWS Spot Instances to request spare computing capacity for up to 90% off the On-Demand price.

### 3.9.1 AWS Spot Pricing Overview

A description of spot pricing and information on implementing it.

### 3.9.2 What is Spot Pricing

Amazon EC2 Spot Instances offer spare compute capacity available in the AWS cloud at steep discounts compared to On-Demand instances. Spot Instances can be interrupted by AWS with two minutes of notification when AWS needs the capacity back. AWS can interrupt your Spot Instance when the Spot price exceeds your maximum price, when the demand for Spot Instances rises, or when the supply of Spot Instances decreases.

The recommendation is to avoid running critical or long running jobs on spot instances as jobs may be killed when spot instances are preempted.

### 3.9.3 Implementing AWS Spot Pricing

Create an AWS bursting scenario. Once the bursting scenario is created, select the bursting scenario and choose to set up spot instances. A list of machine types are displayed that can be enabled for spot pricing:

Spot Instances

Cancel

Save

Instance type name ^	Core	Mem	GPU	Price	Current Spot Price	Max Spot Price	Enable for spot
<input type="text" value="Search by name"/>							
a1.2xlarge	8	16 GB	0	0.204 \$/h	0.039 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
a1.4xlarge	16	32 GB	0	-	0.079 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
a1.large	2	4 GB	0	0.051 \$/h	0.010 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
a1.medium	1	2 GB	0	-	0.005 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
a1.xlarge	4	8 GB	0	-	0.020 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
c4.2xlarge	8	15 GB	0	-	0.091 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
c4.4xlarge	16	30 GB	0	-	0.148 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
c4.8xlarge	36	60 GB	0	15.100 \$/h	0.292 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
c4.large	2	3.75 GB	0	-	0.018 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>
c4.xlarge	4	7.5 GB	0	-	0.040 \$/h	<input type="text" value="\$/h"/>	<input type="checkbox"/>

Previous

Page1 of 6

25 rows

Next

Figure 3-51:Spot Instances

#### Instance type name

Name of the instance type (machine type, shapes or flavors) as defined by the cloud provider.

#### Core

Number of CPUs available for this instance type.

#### Mem

Amount of RAM available for this instance type.

#### GPU

Number of GPUs available for this instance type.

#### Price

On-demand price. With On-Demand instances, you pay for compute capacity by per hour or per second depending on which instances you run. No longer-term commitments or upfront payments are needed. You can increase or decrease your compute capacity depending on the demands of your application and only pay the specified per hourly rates for the instance you use.

### Current Spot Price

Currently, available spot price. With spot instances, you pay the spot price that's in effect for the time period your instances are running. Spot instance prices are set by Amazon EC2 and adjust gradually based on long-term trends in supply and demand for Spot instance capacity. Spot instances allow you to request spare Amazon EC2 computing capacity for up to 90% off the On- Demand price.

### Max Spot Price

Maximum amount that your site is willing to pay to continue using the spot instance. Once this price is exceeded the spot instance can be interrupted by AWS with two minutes of notification.

### Enable for spot

Machine type is enabled for spot pricing.

Choose which instance types that you want for spot pricing and enter a maximum price that you are willing to pay to continue using the spot instance.

A scenario must be added to the cloud bursting hook configuration file for every instance type selected for spot pricing and the scenario must be enabled as preemptible.

```
"preemptable": true
```

## 3.9.3.1 Cloud Bursting Hook Scenario Example

Two instance types are selected for spot pricing:

Instance type name ^	Core	Mem	GPU	Price	Current Spot Price	Max Spot Price	Enable for spot
<input type="text" value="Search by name"/>							
a1.2xlarge	8	16 GB	0	0.204 \$/h	0.039 \$/h	0.045 \$/h	<input checked="" type="checkbox"/>
a1.4xlarge	16	32 GB	0	-	0.079 \$/h	\$/h	<input type="checkbox"/>
a1.large	2	4 GB	0	0.051 \$/h	0.010 \$/h	\$/h	<input type="checkbox"/>
a1.medium	1	2 GB	0	-	0.005 \$/h	0.01 \$/h	<input checked="" type="checkbox"/>
a1.xlarge	4	8 GB	0	-	0.020 \$/h	\$/h	<input type="checkbox"/>
c4.2xlarge	8	15 GB	0	-	0.091 \$/h	\$/h	<input type="checkbox"/>
c4.4xlarge	16	30 GB	0	-	0.148 \$/h	\$/h	<input type="checkbox"/>
c4.8xlarge	36	60 GB	0	15.100 \$/h	0.292 \$/h	\$/h	<input type="checkbox"/>
c4.large	2	3.75 GB	0	-	0.018 \$/h	\$/h	<input type="checkbox"/>
c4.xlarge	4	7.5 GB	0	-	0.040 \$/h	\$/h	<input type="checkbox"/>

Figure 3-52:Spot Instances

Add the following scenario to the cloud bursting hook configuration file:

```
"aws_scenario_1": {
 "api_key": "API-KEY-HERE",
 "cloud_default_image": "<CloudDefaultImage>",
 "cloud_max_instances": 20,
 "max_nodes_per_burst":50,
 "cloud_node_wait_timeout":180,
 "preemptable": true
}
```

## 3.9.4 Choose Spot Instances

Choose instance types for spot pricing and set the maximum spot price.

Before you can choose instances for spot pricing you must have created an AWS bursting scenario.

1. Log in to Cloud.
2. Click the Cloud tab.
3. Under Infrastructure, click Bursting.
4. Select an AWS bursting scenario by clicking on its name.
5. Choose one of the following options:
  - If spot pricing has not yet been set up, click Set up spot instances.
  - If spot pricing instances have already been enabled, click Edit spot instances.

A list of spot instances are listed.

Spot Instances								Cancel	Save
Instance type name ^	Core	Mem	GPU	Price	Current Spot Price	Max Spot Price	Enable for spot		
Search by name

Figure 3-53:Spot Instances

6. Scroll through the list by:
  - Clicking the Previous and Next buttons to scroll through the list.
  - Entering a page number in the Page field and pressing ENTER to jump to a specific page.
  - Entering search criteria in the Search by name field to filter the list of instance types by name.
7. Select an instance type for spot pricing by enabling Enable for spot to the far right of the instance type name.
8. To disable spot pricing for an instance type, disable *Enable for spot*.
9. Enter a maximum spot price that you are willing to pay for the instance type.
10. Repeat steps 6 through 8 to choose additional instance types for spot pricing.
11. Click Save.

### 3.9.5 Add Scenarios to the Cloud Bursting Hook

Add scenarios to the cloud bursting hook configuration file to configure PBS Professional to use spot instances.

Configuring the hook must be done as root or as a user with sudo permissions using the sudo command.

1. Export the cloud bursting hook configuration to a file:
 

```
qmgr -c "export hook cloud_hook application/x-config default" > FILENAME
```

---

Where FILENAME is the name of the file where the hook configuration is written.

```
qmgr -c "export hook cloud_hook application/x-config default" > config.json
```

2. Edit the file.
3. Add the AWS scenario to the scenario container. Note that you can create a single scenario with multiple spot instance types or create a scenario for each spot instance type.
  - a. Set the value of `api_key` to the token generated for the bursting scenario.
  - b. Set the value of `cloud_default_image` to OS image that should be used for bursting. This OS image is used if the image is not requested as part of the job submission request.
  - c. Set the value of `cloud_max_instances` to the maximum number of instances that can be made available in the cloud.

Must be expressed as an integer greater than zero. This value must be specified otherwise the cloud bursting hook is rejected.
  - d. Set the value of `max_nodes_per_burst` to the maximum number of nodes allowed to burst in a single hook cycle.
  - e. Set the value of `cloud_node_wait_timeout` to the maximum time to wait for freshly burst node to become usable.

Must be expressed as an integer whose units are in seconds. Default is 180 seconds. You can set this to a higher value, but a lower value defaults to 180 seconds.
  - f. Set `preemptable` to `True`.
4. Save the file.
5. Re-import the hook with the updated configuration values:

```
qmgr -c "import hook cloud_hook application/x-config default FILENAME"
```

Where FILENAME is the name of the file containing the hook configuration.

```
qmgr -c "import hook cloud_hook application/x-config default config.json"
```

6. Enable the cloud bursting hook.

The cloud bursting server periodic hook is disabled by default.

```
qmgr -c "set hook cloud_hook enabled=True"
```

# Running Cloud Jobs

## 4.1 Introduction

Jobs are submitted to one or more designated cloud queues, and a server periodic hook monitors the cloud queues, estimates the demand for cloud nodes, and dynamically adjusts the number of nodes by bursting or unbursting as needed.

You can choose any of the instance types allowed by the administrator via `CLOUD_INSTANCE=<instance type>`.

You can choose an OS image with `CLOUD_IMAGE=<name of image file>`.

## 4.2 Sample Job Script: Cloud Job

The following script is simply a job requesting 10 minutes of walltime, it will sleep for 1 minute (or tune `$sleep_time` as appropriate) and then exit. It requests `cloudq`; adjust the name depending on previous configuration. You can save the following job script as `sleep.sh`. Then you can submit it to PBS:

```
qsub sleep.sh
```

### 4.2.1 Contents of Sample Cloud Job Script

```
#!/bin/bash
#PBS -N testjob
#PBS -j oe
#PBS -m n
#PBS -q cloudq
#PBS -l select=1:ncpus=2:mem=16mb
#PBS -l walltime=0:10:00
sleep_time=60
cmd="sleep $sleep_time"
echo $cmd
$cmd
exit
```

### 4.2.2 Viewing Job Output

When the job completes you should see the job's output. This will appear where the job was submitted.

## 4.3 Logging into Cloud

To log into Cloud, go to the Cloud interface in your web browser:

```
http://<server>:9980/pbspro-cloud/#/login
```

# Introduction to Budget

## 1.1 Introduction

Budget is a High Performance Computing (HPC) resource budgeting tool for project stakeholders. Budget provides flexibility and control over how available compute resources are used over medium- and long-term periods, and is tightly integrated with the job management mechanisms of PBS Professional.

### 1.1.1 Managing Resource Usage

PBS Professional lets you submit jobs once the architecture and systems of a HPC site are in place. Budget lets you allocate credit to PBS Professional jobs. An allocation is a consumable resource available for use by projects. Each allocation is linked to projects and fixed time periods. As the resources are consumed, the allocation is depleted. Allocations can be made for compute resources, budget resources, or a combination of both.

Budget works like a bank by providing a form of customized currency. It records usage of HPC resources through PBS Professional, as transactions in that currency. HPC owners (investors) provide departments or business units consisting of managers with an initial amount to be used over a period of time. Managers allocate this amount to projects (joint accounts) and individuals (individual accounts) for their activities. For example, a university might give the Physics department 100000 units for a year, and a part of that might be distributed to specific research projects or individual researchers for Quarter 1 and Quarter 2 of the year. The project teams and individual users can then run their jobs thereby consuming those budgets. They can balance their budgets by tracking consumption in the time periods and determine how they want the system to be used.

An initial amount of currency is granted to a user or project to submit jobs. Based on the resources requested by a job, Budget calculates the amount of currency required for the job to complete. Budget then authorizes the amount from the user or project and allows the job to run.

Once the job is finished, balance from the authorized amount is reconciled to the user's account based on the resources consumed. Every transaction is recorded. These transactions are tracked over particular time frames, usually for a month, quarter, or year. All transaction information is stored in a database allowing extensive statistical allocation tracking. The reports of these transactions enable managers and investors to budget their resource usage. The Budget framework holds all the account and transaction information in its database.

### 1.1.2 Currency

The customized currency could be actual dollars or it could be a compute resource, e.g. CPU hours, GPU hours, or whatever resource-based calculation an HPC site would like to use. PBS queries Budget through hooks. The hook sets the definition of the currency. The amount of each job's allocation charge is associated with the amount of resources used by the job and the amount of time it was used for. It can be configured to charge varying amounts based on the type of compute resources used, priority of the job, day of the week, or time of day when the resources were used. The hook also determines whether you have permission, and the required currency, to consume the resource you request. You can budget the usage of external resources such as storage by setting quotas on them.

You can define various different currencies, and allocate different amount to different groups and users.

## 1.2 Budget Terminology

### Account

The entity against which allocations are defined, credited, and debited.

Defined by the Budget administrator; can be specific to the needs of the client.

Allocations (currency) are deposited into the account by a Manager for a specified time period and service unit.

Currency is debited from the account when users who are assigned to the account run jobs that use the currency.

Currency is usually tied to a resource such as CPU hours, GPU hours, etc.

There are two types of accounts:

#### Project

An entity that represents a project or workflow within a department or business unit, etc. The currency deposited into the account can be used by any users assigned to the account.

#### User

An entity that represents an individual. The currency deposited into the account can only be used by the individual assigned to the account.

### Allocation

A consumable resource available for projects and users. It is linked to projects and extends for a fixed time period. As the resources are consumed, the allocation is depleted. Allocations can be made for compute resources, budget resources, or a combination of both.

### Budget Resource

Currency mapped to a compute resource, e.g. 1 CPU-hour = \$10 1 GPU-hour = \$25. For a budget resource, users specify the currency budget and consume any of the mapped PBS resources.

### Compute Resource

An arithmetic formula involving a PBS resource and time. For example, the PBS resources `ncpus` and `walltime` together make up the compute resource CPU-hours.

Other examples are GPU-hours, memory-hours, etc.

### Cluster, PBS Complex

One or more machines managed by PBS Professional. Projects are associated with an HPC cluster and funding for those projects is administered by Budget.

### Element

Used to refer to a part of Budget, such as a transaction or configuration. Can be something associated with an entity, such as a limit on a service unit. This is a blanket term and includes entities.

### Entity

A data structure in Budget. A period, cluster, service unit, user, project, group, role.

### Group

An entity that represents an organization structure such as a department, a business unit, etc. Group investors provide funds to the group, and group managers pass these funds to user and project accounts.

### Instance

An installation of Budget; described by a name and the hostname or IP address of the machine where Budget is installed.

---

**Period**

Time duration for which an allocation is made, and against which it is reported.

Defined by the Budget administrator; can be specific to the needs of the client.

Examples: a year, a quarter within a year, a month within a year.

**Queue Weight**

Each queue has its own priority, which may be the same as or different from that of other queues. Compute resources or budget resources can be depleted at different rates at different queues. You can use queue priority in the formula as a weighting mechanism.

**Role**

Roles define access to the features of Budget.

**Admin**

Configures Budget.

**Investor**

Deposits service units to a group.

**Manager**

This role is associated with a group. This role adds or withdraws currency for user and project accounts.

**Teller**

Performs all acquire and reconcile transactions on behalf of users.

The Teller has full permissions for transactions and can read all other projects, accounts, groups, etc.

**User**

PBS users who are authorized to run jobs for a project and consume currency allocations.

**Standard Service Unit**

Single unit of a compute resource, a budget resource, or a combination of both.

Defined by the Budget administrator; can be specific to the needs of the client.

Example: CPU-hours, GPU-hours, dollars

**Dynamic Service Unit**

A unit of an external compute resource such as storage.

Limits can be set on dynamic service units in order to define quotas. If a quota is exceeded, jobs that depend on that service unit do not run.

**Transaction**

An action that takes place for a specific purpose:

**Credit**

Currency is added to an account.

**Debit**

Currency is subtracted from an account.

**Refund**

A Budget administrator refunds currency to an account.

**Job Acquire**

Currency is allocated to the job when the job is submitted.

**Job Release**

Transaction that occurs when a job completes.

## 1.3 Relationships in Budget

### 1.3.1 Groups, Investors, Managers

Groups in Budget represent organizational entities such as departments or businesses. For example, an organization might have multiple departments including engineering, systems, and software, which get funding from investors (e.g. the CFO). The departments (groups) can then fund projects.

Group investors deposit funds to the group budget pool. Group managers transfer funds to and from user and project accounts. A group is at least one investor who can contribute currency to the group's budget pool, and at least one manager who can use the budget pool to fund users and/or projects.

Linking to a group means joining the group. A group can have multiple investors, and investors can be linked to multiple groups. Investors must be part of a group in order to invest in that group. A group can have multiple managers, and managers can be linked to multiple groups. Many groups can fund a single project and a single group can fund many projects.

The group budget pool does not have any defined period. The amount in the budget pool is available for an infinite amount of time.

When an investor is unlinked from a group, or a group is unlinked from a project, funds are kept with the group or project, and become unusable. Therefore investors should withdraw before unlinking. The group manager can transfer these funds to another owner or group and make them usable again.

A group manager can transfer funds from one group to another within a project, or between two projects.

Project and user accounts can be part of multiple groups.

### 1.3.2 Investing and Consuming Funds

Investing in a user or group means dispensing currency to that user or group.

Funds are consumed when jobs are submitted by authorized users and projects.

The amount each investor dispenses to a group is tracked. Investors cannot withdraw more than the amount they disperse to a group.

There is no limit on the funds a manager can allocate to a project or user. A single manager can use the entire budget of the group. A allocation to an account is linked to a period, and the allocation expires at the end of the period. A group manager can withdraw funds from one period and allocate them to a different period.

A service unit is a currency. A user or project can consume multiple currencies.

## 1.4 Job and Credit Workflow

1. User submits job
2. Budget validates credit of the project or user, depending on whether job is part of project
3. Job is queued at PBS server (queuejob hook)
4. When job is sent for execution, a runjob Budget hook authorizes credit, and puts needed credit in escrow
5. Job runs at execution host
6. When job finishes, an execjob\_epilogue hook debits credit that was used by job and returns excess to user or project

---

## 1.5 Service Units

### 1.5.1 Standard Service Units

A standard service unit tracks an internally managed resource such as CPU-hours. Standard service units are a measure of resource usage multiplied by time of use such as CPU-hours or GPU-hours. Standard service units can be treated like a currency. For example, the dollars used can be a calculation representing any resource, such as CPU-hours, GPU-hours, and memory usage.

Budget tracks the consumption of service units. If sufficient service units are available, jobs are allowed to run. When a job runs, the consumed amount of service units is deducted from the project or user account. The Budget hook contains the formula for calculating standard service units.

### 1.5.2 Dynamic Service Units

A dynamic service unit is a service unit that tracks an external resource such as storage. At a given point in time, a dynamic service unit is a snapshot of the current usage level of a given external resource. This usage level is reported by an external script that you write. You would normally run the script as a cron job, where it calls `amgr updatedynamicvalues`, which updates the value of the dynamic service unit. See [section 5.2.1.5, “Updating Dynamic Values”, on page 29](#).

A group manager can apply limits to consumption of dynamic service units for project and user accounts. These limits have to be set for specific periods. Limit periods can be nested; for example you can set a limit for a year, and also set limits for quarters in the year. If there is no limit, the limit defaults to zero. A job’s most recently reported usage is compared against the current limit; previous usage is not taken into account. If a limit is reached the job is not allowed to run. The job will run again if the limit is increased or the resource usage is reduced.

### 1.5.3 Rules for Using Service Units

When you create a service unit, the default type is `SU_STANDARD`. You can specify standard or dynamic service units via the `-t <service unit type>` option to the `amgr add serviceunit` command; see [section 5.2.1.3, “Adding a Service Unit”, on page 28](#). The type for dynamic service units is `SU_DYNAMIC`.

- You can change the type of a service unit, but there are restrictions:
  - You can change standard to dynamic only when no transactions have taken place
  - You can change dynamic to standard only when no updates have been made to the external `dynamicvalue`
- In the budget hook configuration file, you can use only standard service units.
- An active dynamic service unit must have a limit set in order for jobs to use it
- If you apply a limit directly to a period, it does not inherit the limit from its parent
- If you apply a limit to a period, all child periods that are not directly limited inherit the limit; similarly, limits on child periods are inherited by children of those child periods, when no direct limits have been set
- When you create a new child period, it inherits its limit from its parent
- Only group managers can update `dynamicvalues`.

### **1.5.3.1 Storage Quotas via Dynamic Service Units**

You can limit usage of external storage by setting quotas on dynamic service units that track external storage. Group managers can define a limit (i.e. amount of storage in GB) that a project or user can use during a specific period. Jobs belonging to the project or user can run during the period specified in the dynamic service unit limit as long as usage is below the dynamic service unit limit. When the usage value reaches the limit, running jobs are stopped for the project or user in that period. Jobs will run again when the usage is reduced below the limit or when the limit is increased.

# Installing Budget

## 2.1 Supported Platforms for Budget

- CentOS 7
- SLES 15

## 2.2 Prerequisites

### 2.2.1 Altair Prerequisites

Altair License Manager 14.5 or newer

PBSProNodes 20.0 license features

PBS Professional 2020.1, installed and running

### 2.2.2 Third-party Prerequisites

`docker-ce v19.x` or later

`python3`

`python3-pip`

### 2.2.3 Required Accounts

- Administration requires a Budget administrator. We recommend that this be `pbsadmin`. This user should not be `amteller`.
- The Budget database requires the `pbsdata` user.
- Budget requires a teller (`amteller`) to process transactions through the Budget hook. This user should not be `pbsadmin`. This user does not have to be root or administrator.
- Users who submit jobs to PBS Professional have to exist in the system where Budget is installed, but these users can be added to Budget after installation.

#### 2.2.3.1 Configuring Accounts for Budget

1. Add a user called `pbsdata` for the Budget database (PostgreSQL) and set a password.

```
adduser -u 900 pbsdata
```

```
passwd pbsdata <password>
```

The pbsdata user should have an ID <1000 so that any processes which run under this user are protected from the Out Of Memory (OOM) killer and run with the correct level of privilege.

2. Add pbsadmin as the Budget administrator

```
adduser -u 901 pbsadmin
passwd pbsadmin <password>
```

3. Add the amteller user

```
adduser -u 902 amteller
passwd amteller <password>
```

## 2.3 Recommended Configurations

Head node and service node can be one of either:

- Both on premises
- Both in cloud

Do not put one on premises and one in the cloud.

### 2.3.1 Recommended Configuration for Larger Installations

For larger installations using on premises hosts:

- Hosts on premises for PBS server, scheduler, some MoM daemons, cloud service node
- Head, service, and first N execution nodes are on premises
- Extra execution nodes can be burst
- On head node, PBS and Budget
- On service node
  - AMS designed to run in container
- VPN connection to the cloud you will use
- Client commands go on any Linux host

Notes:

- You may not want Docker on the head node, because it may impose too high a load.
- All components are mix-and-match (with Docker restriction).
- The AMS module may cause too much load to be run on the head node.
- You don't need to configure additional `pbs_comm` daemons for cloud nodes, because cloud can't cause enough throughput to need one.
- For PBS configuration instructions, see the *PBS Professional Administrator's Guide*.

---

## 2.3.2 Recommended Configuraton for Smaller Installations

For smaller installations cloud-only installations where the workload is low enough:

- All PBS components can be hosted in the cloud
- Cloud headnode, running PBS Professional server and Budget module
- All components can run on the same node
- You can run Docker on the same node as the PBS components
- Client commands go on any Linux host, but a user must be able to reach the Budget port on the cloud host

Notes:

- No VPN is required for this configuration.

## 2.3.3 Software Components

- Budget module
- Budget client commands
- PBS Professional server/scheduler(s)/comm
- PBS Professional client commands
- Authentication module

---

## 2.4 Installation Steps

1. Log in as root.
2. Install utilities and docker:

```
yum install -y yum-utils
yum-config-manager --add-repo https://download.docker.com/linux/centos/docker-ce.repo
yum install docker-ce docker-ce-cli containerd.io
systemctl enable docker
systemctl start docker
yum install python3 python3-pip
```
3. Copy installer tar files to your host machine:

```
ams_installation.tar.gz
budget-manager-server-centos7-2020.1.1.tar.gz
```
4. Install the AMS module to provide the Budget security framework. As the Budget module points to this module (AMS) as a web service it can be installed on a machine other than the PBS/Budget server.
  - a. Install AMS:

```
tar xvfz ams_installation.tar.gz
cd ams-installation
python3 -m pip install --upgrade --ignore-installed pbsworks-packager/
/usr/local/bin/pkgmgr
```

(Please stay in the ams installer directory for this step)
  - b. Answer the questions in the dialogue:
    - Choose option: 0
    - Hit Enter until license agreement complete and then answer Yes to accept.
    - Select Enter to continue
    - Choose Option 1 (Provide server hostname/IP address)  
<hostname>  
<ip>
    - Choose Option: 0 (Skips providing any more machine details)
    - Install Location: <hostname>
    - Authentication Server: <hostname>
    - Authentication Port: Accept Default (If alternative to default 22 for sshd is used then provide alternative port ID)
    - Provide Admin User: pbsadmin
    - Install Path: Accept default
  - c. Once installation completes check the AMS service status:

```
systemctl status altaircontrol
```
5. Install the Budget module:

```
tar xvfz budget-manager-server-centos7-2020.1.1.tar.gz
cd am
```
6. Edit and configure the /etc/am.conf file.

```
AM_PORT=8000
```

---

```
AM_EXEC=/opt/am
AM_HOME=/var/spool/am
AM_WORKERS=2
AM_DBUSER=pbsdata
AM_DBPORT=9876
AM_AUTH_ENDPOINT=9100@<AMS server host>
AM_LICENSE_ENDPOINT=6200@<ALM host>
AM_SERVER=<Budget host>
```

7. Set up the environment. Replace AM\_HOME with path from /etc/am.conf:  

```
export PATH=/$AM_HOME/python/bin:$PATH
```
8. Run the Budget module installer:  

```
./install -u pbsadmin
```
9. Start Budget:  

```
/etc/init.d/am start
```
10. After setting up the cluster and installing Budget, add the amteller user to Budget:  

```
amgr add user -n amteller -A begin_period -c <cluster-name> -r teller
```

# Configuring Budget

## 3.1 The Budget Configuration File

The configuration file for Budget is `/etc/am.conf`:

```
AM_PORT=8000
AM_EXEC=/opt/am
AM_HOME=/var/spool/am
AM_WORKERS=2
AM_DBUSER=pbsdata
AM_DBPORT=9876
AM_AUTH_ENDPOINT=9100@<AMS server host>
AM_LICENSE_ENDPOINT=6200@<ALM host>
AM_SERVER=<Budget host>
```

## 3.2 Configuring the Budget Hook

Budget works like a bank by providing a form of customized currency. Budget records usage of HPC resources by PBS Professional jobs, as transactions in that currency. The customized currency could be actual dollars or it could be a compute resource, e.g. CPU-hours, GPU-hours, or whatever resource-based calculation a site needs. The PBS Budget hook contains the definition of the currency. The amount of currency charged to a job is calculated from the amount of resources used by the job and the amount of time it was used for. The hook can be configured to charge varying amounts based on type of compute resources used, priority of the job, day of the week, or time of day when the resources were used. The hook also determines whether the job owner has permission or the required amount of currency to consume the resource requested.

How to configure the Budget hook:

1. Add the path to the PBS binary to the environment variable PATH:  
`export PATH=$PATH:/opt/pbs/bin/`
2. Check the status of PBS:  
`systemctl status pbs`
3. Create a resource called `am_job_amount` of type string:  
`qmgr -c "c r am_job_amount type=string"`
4. Create a custom resource called `am_job_cache` of type string:  
`qmgr -c "c r am_job_cache type=string,flag=m"`
5. Create a hook called `am_hook`:  
`qmgr -c "c h am_hook"`
6. Set the hook to run for the events `queuejob`, `runjob`, `modifyjob`, `movejob` and `execjob_epilogue`:  
`qmgr -c "s h am_hook event='queuejob,runjob,execjob_epilogue,modifyjob,movejob'"`
7. Set the order of the hook to be the highest (last to run). This will ensure the hook will run after all other hooks for each of the events. In the example below we set it to 1000:  
`qmgr -c "s h am_hook order=1000"`
8. Create a periodic hook called `am_hook_periodic`:  
`qmgr -c "c h am_hook_periodic"`
9. Set the hook to run for the `periodic` event:  
`qmgr -c "s h am_hook_periodic event=periodic"`
10. Set a frequency, for example 120 seconds, for the periodic hook:  
`qmgr -c "s h am_hook_periodic freq=120"`
11. Define the service unit. Use the same name in Budget and in the hook. Do not use blank spaces or special characters in the service unit name. You can use underscores. Edit the JSON file placed by the installer at `/opt/am/hooks/pbs/am_hook.json`. For example:  
`vi /opt/am/hooks/pbs/am_hook.json`

For a simple “cpu\_hrs” service unit, use:

```
{
 "auth_user": "amteller",
 "constants":{
 "ncpus" : "job.ncpus",
 "walltime" : "job.walltime"
 },
 "formulas":{
 "cpu_hrs" : "ncpus*walltime"
 }
}
```

12. Import the am\_hook using the am\_hook.py file placed by the installer at /opt/am/hooks/pbs/:

```
qmgr -c "i h am_hook application/x-python default /opt/am/hooks/pbs/am_hook.py"
```

13. Import the am\_hook\_periodic hook using the am\_hook.py file placed by the installer at /opt/am/hooks/pbs/:

```
qmgr -c "i h am_hook_periodic application/x-python default /opt/am/hooks/pbs/am_hook.py"
```

14. Enable both the hooks:

```
qmgr -c "s h am_hook enabled=true"
qmgr -c "s h am_hook_periodic enabled=true"
```

15. Import the JSON file for both the hooks:

```
qmgr -c "i h am_hook application/x-config default /opt/am/hooks/pbs/am_hook.json"
qmgr -c "i h am_hook_periodic application/x-config default /opt/am/hooks/pbs/am_hook.json"
```

16. The hook alarm time is set to 30 seconds by default. If the job submission rates are high, increase the hook alarm time:

```
qmgr -c "s h am_hook alarm=90"
```

### 3.2.1 Rules for Configuring Hooks

Here are some important points to keep in mind while configuring the hook:

- The service unit name should match the name defined in the hook. Do not use blank spaces or special characters in the service unit name. You can use underscores.
- Put all standard service units in the hook configuration file.
- Apart from PBS Professional job attributes and node attributes, you can define constants with the prefix “CONST\_”. Constants in hook formulae should be defined as floating point numbers.
- Use PBS attributes of type float or int.
- The walltime, cput and eligible\_time resources are of duration format (hh:mm:ss). The hook converts the value of these to seconds when used in the formula for the service unit. For example, if a job’s walltime is two minutes, the value used in the formula is 120.
- The mem and vmem resources are of size format (3b, 20kb etc.). The hook converts their values to kb in the service unit formula.
- For jobs that run on multiple vnodes, the hook uses the sum of the resources used. The hook does not support calculation of variable rates on multiple vnodes.
- Do not add resources to a formula when jobs are running. To add resources, drain the system of jobs during a maintenance window and update the formula, then put the system back into production.
- The method to select job objects in hooks is: `job.Resource_List[‘ncpus’]`. In Budget, the equivalent method is simplified to: `job.ncpus`
- The other aspects are internally handled by Budget. You can use logical operators (AND and OR), conditional operators ( >, >=, <, <=, ==, !=) with CONST\_ variables and hook attributes.
- While accessing server, queue, and node-level resources use the hook scripting conventions and omit the single quotes. For example, for `server.resources_available[‘charge_rate’]`, we can use `server.resources_available[charge_rate]`
- The maximum amount of service units an account can hold is 999999999999.99.
- The `am_hook` has to run after all the other hooks for each event. Hence it should have the highest order.
- For example, you can set it to a high order value such as 1000:  
`qmgr -c "s h am_hook order=1000".`
- See the *PBS Professional Plugins (Hooks) Guide* for more information.

## 3.2.2 Hook Examples

### 3.2.2.1 Default Configuration

This is the default configuration file used by the Budget hook. The constants `ncpus` and `walltime` are defined in the constants section, and used in the formulas section to define the `cpu_hrs` default service unit.

```
{
 "auth_user" : "amteller"
 "constants":{
 "ncpus": "job.ncpus",
 "walltime": "job.walltime"
 },
 "formulas":{
 "cpu_hrs": "ncpus*walltime"
 }
}
```

### 3.2.2.2 Multiple Constants and Operators

This is a configuration file using multiple constants and operators. We define the constants `CONST_a`, `CONST_b`, and `CONST_prio`. We use them in the formulas section with logical operators 'and', 'or', the comparison operator '>', and the arithmetic operator '\*'.

```
{
 "constants":{
 "ncpus": "job.ncpus",
 "walltime": "job.walltime",
 "ngpus": "job.ngpus",
 "CONST_a": 2.0,
 "CONST_b": 1.0,
 "CONST_prio": 150
 },
 "formulas":{
 "cost": "(ngpus and node.resources_available[ncpus] or ncpus)*walltime*(
 queue.Priority > CONST_prio and CONST_a or CONST_b)"
 }
}
```

### 3.2.2.3 Multiple Service Units

We define three different service units: `cpu_hrs`, `gpu_hrs`, and `mics_hrs`.

```
{
 "constants":{
 "ncpus" : "job.ncpus",
 "walltime" : "job.walltime",
 "ngpus" : "job.ngpus",
 "nmics" : "job.nmics"
 },
 "formulas":{
 "cpu_hrs" : "ncpus*walltime",
 "gpu_hrs" : "ngpus*walltime",
 "mics_hrs" : "nmics*walltime"
 }
}
```

## 3.3 Configuring Failover for Budget

Failover is the capability to switch over from the primary Budget server to the secondary Budget server when the primary server becomes unavailable. When the primary Budget server is unable to run, a secondary Budget server can be manually started to switch over and continue operations.

To create a failover configuration, set up `AM_HOME` at a shared location and run the server processes on your primary server host. If the Budget primary server (Server 1) is unable to run, you can use a secondary failover server (Server 2) to access the shared location and run the server processes again.

1. Install NFS utilities on both the server hosts to create a shared location:  
`yum install nfs-utils nfs-utils-lib`
2. Mount the shared location and ensure that both the servers have write access to this location:

```
mount dataserver:/export /export
```

3. Ensure that the same version of PostgreSQL is installed on both the servers.
4. Install Budget on the primary server (Server 1)
  - a. Edit `am.conf` and set `AM_HOME` to `/export/am`
  - b. Install Budget using install script
5. Install Budget on secondary server (Server 2)

- a. Edit `am.conf` and set `AM_HOME` to `/tmp/am`
- b. Install using install script
- c. Once installation is successful, stop Budget  
`/etc/init.d/am stop`
- d. Edit `am.conf` and change `AM_HOME` to `/export/am`  
`AM_HOME=/export/am`

**CAUTION:** Do not start Budget on the secondary server. If two instances of Budget are active at the same time, the database will get corrupted. Ensure that only one instance of Budget is active at a time.

---

### 3.3.1 Switching to Secondary Budget Server

If the primary server (Server 1) is unable to run, switch over to the secondary server (Server 2):

1. Log in to the secondary server host (Server 2) and update the hostname of Server 2 to that of Server 1  
Alternatively, you can update the `/etc/am.conf` file on the PBS server host and all the clients to point to the hostname or IP address of Server 2.
2. Ensure that the shared location is accessible from Server 2.
3. Start the Budget service  
`/etc/init.d/am start`

To access Budget hosts, use hostname instead of IP address in the configuration files.

## 3.4 Configuring Budget for Peer Scheduling

In a peer scheduling setup, different PBS complexes are set up to automatically run each others' jobs to dynamically load-balance jobs across the complexes. Budget needs to be aware of all the clusters in a peer scheduling environment.

To use Budget when running jobs in multiple clusters in a peer scheduling environment:

1. Configure the Budget hook in all the peer scheduling clusters.
2. Add the clusters involved in peer scheduling to Budget using `amgr add cluster`. See [section 5.2.1.2, “Adding a Cluster”, on page 27](#).
3. Add the peer scheduling clusters to the project account or user account to run jobs via `amgr update <user or project> -c <cluster>`; see [section 5.2.3.1, “Updating Projects”, on page 36](#) and [section 5.2.3.2, “Updating Users”, on page 37](#).

# Authentication for Budget

## 4.1 Authenticating Users

Budget users are required to log in to Budget using their local host credentials to run commands.

Budget uses AMS to retrieve tokens, verify them and authenticate users. Every Budget request has an authorization token (JSON Web Token) with a header and Budget decrypts this token to authenticate the user and send back a HTTP response.

1. To begin using the Budget CLI, log in to the application using the command:

```
amgr login
```

2. Enter your local host password.
3. After logging in, you can use the Budget commands.
4. To close your session, log out of Budget by using the command:

```
amgr logout
```

### 4.1.1 Authenticating Budget

While installing Budget, the Budget server is registered as a client in AMS. A `client_id` and `client_secret` is returned from AMS. This is stored in the Budget database and retrieved when Budget is launched. The authentication mechanism will use the `client_id` and `client_secret` as auth headers for login and logout requests. The request module decrypts the tokens received during the request. The username for the login is the shell's current user.

## 4.2 Budget and PBS Authentication

In Budget, an admin user with the teller role performs all acquire and reconcile transactions on behalf of the users. In the hook configuration file `am_hook.json` located at `/opt/am/hooks/pbs/`, the teller is specified as the value of the `'auth_user'` key.e.g. `"auth_user": "amteller"`.

## 4.2.1 Prerequisites

- The teller user should be a dedicated user for the sole purpose of the teller role.
- Budget should have an authorized user (e.g. amteller) assigned with the “Teller” role. This role has all permissions on the transaction model and read access to all other models.
- Configure password less SSH between PBS Server and Budget server for the amteller user.
- Home directory for authorized user (e.g. pbsadmin and amteller) should exist on the PBS Server machine.
- Disable requiretty for the amgr sshlogin command. Add these entries to the /etc/sudoers file.  
`Cmd_Alias AM_CMD = <AM_EXEC>/python/bin/amgr sshlogin`  
`Defaults!AM_CMD !requiretty`
- On CentOS 6 and Cray (SLES 15) systems, create /etc/locale.conf and add this entry. `LANG=en_US.utf8`
- Teller user (amteller) should be able to SSH to Budget server without a password.

## 4.2.2 Hook Workflow

This section explains how the authorized Teller user influences the hook’s workflow.

### 4.2.2.1 Hook Config File

By default there will be an entry for authorized user under the key ‘auth\_user’ which is pbsadmin. Example of hook configuration file:

```
{
 "auth_user" : "pbsadmin"
 "constants":{
 "ncpus" : "job.ncpus",
 "walltime" : "job.walltime"
 },
 "formulas":{
 "cpu_hrs" : "ncpus*walltime"
 }
}
```

### 4.2.2.2 Budget Call Function

The hook works as follows:

1. Get the authorized username from the configuration file. Default name is pbsadmin.
2. The Budget call function checks whether the token file exists at <auth\_user\_home\_dir>/.am/.amtoken. If the token exists, it is used to make a Budget call.
3. If the token file does not exist, an SSH connection is made to the Budget server.
4. A curl request is made as an authorized user through the ‘authentication/gettoken’ interface to get the token.
5. The token is received and saved inside <auth\_user\_home\_dir>/.am/.amtoken.
6. The saved token is used to make a Budget call.

When the token expires, the last three steps are repeated to get a new token. In this process, if the token cannot be obtained at any point, the Budget call will fail and the job will be rejected.

---

### 4.2.3 Set Up Passwordless SSH from PBS to Budget Server

1. Generate a public authentication key in the PBS server and append it to `~/.ssh/authorized_keys` file in the Budget Server.

2. Log in to the PBS server as pbsadmin

3. Check for an existing SSH key pair

```
ls -al ~/.ssh/id_*.pub
```

If you find existing keys, you can use those or back up the old keys and generate a new one.

4. To generate a new SSH key pair enter the command

```
ssh-keygen
```

5. Copy the contents of the `id_rsa.pub`.

6. Log in into the Budget Server as pbsadmin

7. Check for the `.ssh` directory. If it does not exist, create it:

- a. `mkdir -p .ssh`

- b. `cd .ssh/`

8. Create the `authorized_keys` file in the directory

```
vi authorized_keys
```

9. Paste the content of `id_rsa.pub` that you copied from the PBS Server and save the file.

10. Change the permission of the `authorized_keys` to 600

```
chmod 600 authorized_keys
```

## 4.3 Logging in to Budget

### 4.3.1 Logging In

1. To begin using the Budget CLI, log in to the application:

```
amgr login
```

2. Enter your local host password.

3. After logging in, you can use the Budget commands.

### 4.3.2 Logging Out

To close your session, log out of Budget:

```
amgr logout
```

# Budget Commands

## 5.1 Budget Commands

Budget commands enable you to add, list, update and remove entities from the application. These entities are:

- user
- project
- group
- role
- period
- clusters
- service units

You can use the commands for service units transactions. These transactions are:

- deposit
- checkbalance
- withdraw
- transfer
- precheck
- acquire
- reconcile
- refund

You can use the report commands for projects, users, groups and transactions.

To run Budget commands export the path of the am binaries to the PATH environment variable by using the command:

```
export PATH=$PATH:opt/am/python/bin/
```

### 5.1.1 Using Budget Commands

All Budget commands are prefixed with “amgr”.

#### 5.1.1.1 Finding Command Information

To see a list of Budget subcommands with a single-line description for each command:

```
amgr <enter>
```

To get usage information for a command or subcommand:

```
<command> --help
```

```
<subcommand> --help
```

For example:

```
amgr add --help provides information on how to use the main amgr add command
```

`amgr add period --help` provides information on how to use the `period` subcommand.

Use the `-l` switch for `amgr ls` and `amgr report` commands for more detailed information.

Use the `-j` switch for `amgr ls` commands to get the detailed information output in JSON format. This output can be used by other programs which can process JSON format.

If you enter a command without the required arguments, Budget will prompt you to enter it.

## 5.1.2 List of Budget Commands

**Table 5-1: Budget Entities Commands**

Entities Function	Command	Subcommands
Add Entities	<code>amgr add</code>	<code>user, period, project, group, cluster, serviceunit</code>
List Entities	<code>amgr ls</code>	<code>user, period, project, group, cluster, serviceunit, role</code>
Update Entities	<code>amgr update</code>	<code>user, period, project, group, cluster, serviceunit, dynamicvalue</code>
Remove Entities	<code>amgr rm</code>	<code>user, period, project, group, cluster, serviceunit</code>

**Table 5-2: Budget Service Units Commands**

Service Units Function	Command	Subcommands
Deposit Service units	<code>amgr deposit</code>	<code>user, project, group</code>
Check Balance Service Units	<code>amgr checkbalance</code>	<code>user, project, group</code>
Withdraw Service Units	<code>amgr withdraw</code>	<code>user, project, group</code>
Transfer Service Units	<code>amgr transfer</code>	<code>user, project, group</code>
Precheck Service Units Balance	<code>amgr precheck</code>	<code>user, project</code>
Acquire Service Units	<code>amgr acquire</code>	<code>user, project</code>
Reconcile Service Units	<code>amgr reconcile</code>	<code>user, project</code>
Refund Service Units	<code>amgr refund</code>	<code>user, project</code>

**Table 5-3: Budget Report Commands**

Report Function	Command	Subcommands
Report Commands	<code>amgr report</code>	<code>project, group, transaction</code>

## 5.2 Commands for Managing Budget Elements

The Budget elements commands allow you to list, add, update, and remove entities and other elements.

The Entities subcommands let you create user, role, period, project, group, cluster, and service units.

## 5.2.1 Adding Entities

To add elements to Budget:

**amgr add**

Operates on entities: period, cluster, service unit, user, role, project, group

### 5.2.1.1 Adding a Period

#### 5.2.1.1.i Name

*amgr add period*

#### 5.2.1.1.ii Description

Adds the specified period.

#### 5.2.1.1.iii Syntax

*amgr add period { -n | --name } TEXT { -S | --start-date } TEXT { -E | --end-date } TEXT [{ -p | --parent }] TEXT*

#### 5.2.1.1.iv Parameters

**-n or --name <TEXT>**

Specify the name of the Period.

**-S or --start-date <TEXT>**

Start date of the Period. Format: YYYY-MM-DD.

**-E or --end-date <TEXT>**

End date of the Period. Format: YYYY-MM-DD.

**-p or --parent <TEXT>**

Specify the Parent Period. This is an optional parameter.

A site should plan out the required hierarchy of periods (e.g. Years and Quarters or Years and Months) and create the hierarchy from the top down. Parent (top level) periods cannot be added to the structure once a period has been created at a lower level. The parent period must exist for a sub period to be linked to it.

### 5.2.1.2 Adding a Cluster

#### 5.2.1.2.i Name

*amgr add cluster*

#### 5.2.1.2.ii Description

Adds the specified cluster.

#### 5.2.1.2.iii Syntax

*amgr add cluster { -n | --name } TEXT [{ -a | --active }] [{ True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }]*

**5.2.1.2.iv Parameters**

**-n or --name <TEXT>**

Specify the name of the Cluster. Cluster Name should match the name of the PBS Server hostname. Multiple PBS Servers are supported.

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the Cluster active/inactive. This is active by default.

**5.2.1.3 Adding a Service Unit****5.2.1.3.i Name**

*amgr add serviceunit*

**5.2.1.3.ii Description**

Add a standard service unit to track consumption of computing resources internally in Budget. e.g. `cpu_hrs`.

Add a dynamic service unit to define a limit and manage quotas on external resources.

**5.2.1.3.iii Syntax**

```
amgr add serviceunit { -n | --name } TEXT { -t | --type } TEXT [{ -a | --active }] [{ True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }] [{ -d | --description }] TEXT
```

**5.2.1.3.iv Parameters**

**-n or --name <TEXT>**

Specify the name of the Service unit.

**-t or --type <TEXT>**

Specify the type of Service unit. Should be either `SU_STANDARD` or `SU_DYNAMIC`. Default is `SU_STANDARD`.

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the Service unit as active/inactive.

**-d or --description <TEXT>**

Describe the Service unit.

**5.2.1.3.v Command Example**

The service unit name is used in the Budget PBS hook. Hence, blank spaces are not allowed in the name. It should match the name used in the hook. In the description, multiple words must be wrapped in double quotes. The dynamic service unit name must not be specified in the hook.

Adding a standard service unit:

```
amgr add serviceunit -n cpu_hrs -d "CPU hours"
```

Adding a dynamic service unit:

```
add serviceunit -n luster -t SU_DYNAMIC
```

**5.2.1.4 Apply Limits to Dynamic Service Unit**

Apply limits on dynamic service units.

**5.2.1.4.i Name***amgr limit project**amgr limit user***5.2.1.4.ii Description**

A limit is applied on dynamic service units for a particular period and account (projects or users). The usage of the service unit is reported to Budget by an external application. If the usage reaches the defined limit for the current period, jobs are blocked from running.

**5.2.1.4.iii Effect of Limits on the Period Hierarchy**

- A limit on service unit is applied for a particular period and on an account (project or user).
- A period's limit shall be the same as its parent's limit (if parent limit present) and if admin does not apply any direct limit to it.
- If the administrator applies a direct limit to a period then it will not inherit any changes in limit from its parent.
- Administrator can apply limits to any period.

**5.2.1.4.iv Required Privilege**

Only managers can apply limits. All active dynamic units must have limits available in current period for jobs to run.

**5.2.1.4.v Syntax**

*amgr limit project { -p | --period } { -s | --serviceunit } TEXT FLOAT*

**5.2.1.4.vi Parameters**

*-p or --period <TEXT>*

Period to which the limit is to be applied.

*-s or --serviceunit <TEXT FLOAT>*

Specify the service unit with limits in gb . e.g. “--serviceunit luster 100”

**5.2.1.5 Updating Dynamic Values**

Dynamic values deal with external reporting of dynamic service unit values.

**5.2.1.5.i Name***amgr update dynamicvalues***5.2.1.5.ii Description**

You use an external script to discover the usage of an external resource such as scratch. A dynamic service unit is a service unit that tracks an external resource such as storage. At a given point in time, a dynamic service unit is a snapshot of the current usage level of a given external resource. This usage level is reported by an external script that you write. You would normally run the script as a cron job, where it calls *amgr updatedynamicvalues*, which updates the value of the dynamic service unit. Budget will compare the reported value with the defined limits and allow the jobs run as long as the usage is below the limit.

**5.2.1.5.iii Syntax**

*amgr update dynamicvalues { -v | --value }*

### 5.2.1.5.iv Parameters

**-v or --values <TEXT>**

Specify the dynamic values to update in json formatted string. e.g. -v ‘{“scratch”: {“p1”: {“total”:8, “pbsuser”:4}}}’

- scratch is the dynamic service unit
- p1 is the project account
- total storage consumed is 8 GB
- user pbsuser has consumed 4 GB.

The keyword “total” is required. If user account is provided then only total consumption should be specified.

## 5.2.1.6 Adding a User

### 5.2.1.6.i Name

*amgr add user*

### 5.2.1.6.ii Description

Adds specified user. The users you add to Budget should exist in the Linux system where Budget is installed. When you create a user, you need to assign a role to the user.

### 5.2.1.6.iii Syntax

```
amgr add user { -n | --name } TEXT { -A | --accounting-policy } { begin_period | end_period | proportionate } { -c | --clusters } TEXT { -r | --role } TEXT [{ -h | --groups }] TEXT [{ -a | --active }] { True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }
```

### 5.2.1.6.iv Parameters

**-n or --name <TEXT>**

Specify the name of the user. The username and project name cannot be the same.

**-A or --accounting-policy [begin\_period | end\_period | proportionate]**

Specify the accounting policy for the user.

**-c or --clusters <TEXT>**

Associate clusters to the user.

**-r or --role <TEXT>**

Set the role of the user. Users with Manager role can transfer funds to the user account.

**-h or --groups <TEXT>**

Associate groups to the user account.

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the user account to active/inactive.

### 5.2.1.6.v Command Examples

Adding a user:

```
amgr add user -n joe -A begin_period -c pbs_server -r user -h group01
```

Create a user account and add them to a group as a manager:

```
amgr add user -n user01 -A begin_period -c centos -r manager -h group01
amgr update group -n group01 -M + user01
```

### 5.2.1.7 Adding a Project

#### 5.2.1.7.i Name

*amgr add project*

#### 5.2.1.7.ii Description

Adds specified project.

#### 5.2.1.7.iii Syntax

```
amgr add project { -n | --name } TEXT { -A | --accounting-policy } { begin_period | end_period | proportionate } [{ -S | -start-date }] TEXT [{ -E | --end-date }] TEXT { -c | --clusters } TEXT { -u | --users } TEXT { -h | --groups } TEXT [{ -a | --active }] { True | TRUE | true | t | 1 | False | FALSE | false | f | 0 } [{ -m | --metadata }] <Comma Separated Key Value Pair>
```

#### 5.2.1.7.iv Parameters

**-n or --name <TEXT>**

Specify the name of the project. The project name and username cannot be the same.

**-A or --accounting-policy [begin\_period | end\_period | proportionate]**

Specify the Accounting Policy for the Project account.

**-S or --start-date <TEXT>**

Start date of the Project. Format: YYYY-MM-DD.

**-E or --end-date <TEXT>**

End date of the Project. Format: YYYY-MM-DD.

**-c or --clusters <TEXT>**

Associate clusters to the Project account.

**-u or --users <TEXT>**

Associate users to the Project account.

**-h or --groups <TEXT>**

Associate groups to the Project account. Users with Manager role in a group can add funds to the project.

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the project to active/inactive.

**-m or --metadata**

Metadata for the project. Format: <key1>:<data1>,<key2>:<data2>...

#### 5.2.1.7.v Accounting Policies

Rules for using accounting policy:

- If we create a project with begin\_period the accounts will be charged in the period when the job begins.
- If we create a project with end\_period, the accounts will be charged in the periods when the job ends.
- If we create a project with proportionate, the accounts will be charged in the corresponding periods when the jobs were run.

### 5.2.1.7.vi Multiple Associations to the Project

- Multiple clusters are added in the format `-c c1 -c c2`. If a cluster is added to a project and you submit a job to another cluster, the job will not be queued and will be rejected.
- Multiple users are added in the format `-u u1 -u u2`
- Multiple groups are added in the format `-h h1 -h h2`

### 5.2.1.7.vii Command Example

Add metadata with type:weather and region:asia

```
amgr add project -n proj1 -A begin_period -S '01-02-2019' -E '28-02-2019' -c centos7 -m
type:weather,region:asia
```

## 5.2.1.8 Adding a Group

### 5.2.1.8.i Name

*amgr add group*

### 5.2.1.8.ii Description

Create a group. Investors can transfer funds to the group and managers can transfer funds from the group to projects and user accounts.

### 5.2.1.8.iii Syntax

```
amgr add group { -n | --name } [{ -I | --investors }] [{ -M | --managers }] [{ -a | --active }] [{ True | TRUE | true | t | 1 |
False | FALSE | false | f | 0 }]
```

### 5.2.1.8.iv Parameters

`-n` or `--name` <TEXT>

Specify the name of the Group.

`-I` or `--investors` <TEXT>

Associate investors to the group.

`-M` or `--managers` <TEXT>

Associate managers to the group.

`-a` or `--active` [True|TRUE|true|t|1|False|FALSE|false|f|0]

Set the Group active/inactive. This is active by default.

## 5.2.2 Listing Elements

The Budget “add elements” commands create the starting point. Before them there is nothing that can be listed.

Operates on entities: user, period, project, cluster, service unit, role

To list active records:

```
amgr ls
```

Inactive records are not listed by default. To view inactive records, specify to display the records with active attribute set to false. To display all the clusters which are inactive:

```
amgr ls cluster -a False
```

### 5.2.2.1 Listing Users

Prints group information.

#### 5.2.2.1.i Name

*amgr ls user*

#### 5.2.2.1.ii Description

Lists all the users that exist in Budget, or information about specific users.

#### 5.2.2.1.iii Syntax

```
amgr ls user [{ -n | --name TEXT }] [{ -a | --active }] [{ True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }] [{ -l | --list-info }] [{ -j | --json-info }]
```

#### 5.2.2.1.iv Parameters

-n or --name <TEXT>

Specify the name of the user.

-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]

Specify the status of the user as active/inactive. This is active by default.

-l or --list-info

Display information in list format.

-j or --json-info

Display information in json format.

### 5.2.2.2 Listing Groups

Prints group information.

#### 5.2.2.2.i Name

*amgr ls group*

#### 5.2.2.2.ii Description

Lists all the groups that exist in Budget, or information about specific groups.

#### 5.2.2.2.iii Syntax

```
amgr ls group [{ -n | --name TEXT }] [{ -a | --active }] [{ True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }] [{ -l | --list-info }] [{ -j | --json-info }]
```

#### 5.2.2.2.iv Parameters

-n or --name <TEXT>

Specify the name of the Group.

-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]

Specify the status of the group as active/inactive. This is active by default.

-l or --list-info

Display information in list format.

-j or --json-info

Display information in json format.

### 5.2.2.3 Listing Roles

Prints out role information.

#### 5.2.2.3.i Name

*amgr ls role*

#### 5.2.2.3.ii Description

Prints out all the roles that have been created.

The roles available in Budget are:

admin - can perform all operations. Administrators have user privileges and stakeholder privileges.

investor - can deposit and withdraw service units from associated groups.

manager - can deposit and withdraw service units from associated projects and users.

user - Will be assigned to projects and can run jobs using the project budget.

teller - An admin user role for performing all acquire and reconcile transactions on behalf of users.

When you create a user, you need to assign a role to the user.

#### 5.2.2.3.iii Syntax

*amgr ls role*

#### 5.2.2.3.iv Command Example

To show information on only admin:

```
amgr ls role -n admin
```

For more information about admin, we can use the -l switch.

```
amgr ls role -n admin -l
```

To get this information in JSON format use -j switch.

```
amgr ls role -n admin -j
```

### 5.2.2.4 Listing Periods

Prints out information about periods.

#### 5.2.2.4.i Name

*amgr ls period*

#### 5.2.2.4.ii Description

Prerequisites for listing periods:

- Creation of periods has to be planned. Periods are common across all projects.
- Once transactions are done, periods cannot be extended or deleted.
- A period's start date cannot be extended if transaction exists.
- Same level periods should not overlap.
- Child period range should be within parent period range

#### 5.2.2.4.iii Syntax

*amgr ls period*

### 5.2.2.5 Listing Clusters

Prints information about clusters.

#### 5.2.2.5.i Name

*amgr ls cluster*

#### 5.2.2.5.ii Description

By default, lists all active clusters. You can specify whether you want to see active or inactive clusters. To display inactive clusters:

```
amgr ls cluster -a False
```

#### 5.2.2.5.iii Syntax

*amgr ls cluster [-a <activity level>]*

#### 5.2.2.5.iv Parameters

**-a <TRUE | FALSE>**

Lists all clusters with specified activity level. For activity level, you can specify t, f, true, false, 1, 0, and values are case-insensitive.

### 5.2.2.6 Listing Configurations

Prints the list of Budget configuration options.

#### 5.2.2.6.i Name

*amgr ls config*

#### 5.2.2.6.ii Description

Lists all the configuration options.

Note: As of now we have only one configuration attribute called `data_lifetime` for `SU_DYNAMIC` type of service units. The value of `data_lifetime` is specified in seconds. It is the time for which Budget will wait for an update to `SU_DYNAMIC` (Dynamic Service Unit). If the update does not happen within the specified time, a warning message will be logged in the Budget logs. Jobs are not blocked even if the `data_lifetime` is exceeded.

#### 5.2.2.6.iii Syntax

*amgr ls config [{ -n | --name TEXT }] { -l | --list-info } { -j | --json-info }*

#### 5.2.2.6.iv Parameters

**-n or --name <TEXT>**

Specify the name of the configuration attribute.

**-l or --list-info**

Display information in list format.

**-j or --json-info**

Display information in json format.

### 5.2.2.6.v Sample Output

Sample output of the command

```
SU_DYNAMIC
configuration = {'data_lifetime': 3600}
id = 1
created_user_name = root
created_date = 2020-05-12 09:42:53.312722+05:30
last_updated_user_name = root
last_updated_date = 2020-05-14 15:55:54.339+05:30
```

## 5.2.3 Updating Elements

To update an entity in Budget, use the command:

```
amgr update
```

Operates on entities: user, period, project, group, cluster, service unit, role

### 5.2.3.1 Updating Projects

#### 5.2.3.1.i Name

*amgr update project*

#### 5.2.3.1.ii Description

Update the details of a project.

#### 5.2.3.1.iii Syntax

```
amgr update project { -n | --name } TEXT [{ -A | --accounting-policy }] begin_period, end_period, proportionate [{ -S | -start-date }] [{ -E | --end-date }] [{ -c | --clusters }] <Operator, Comma Separated Strings> [{ -u | --users }] <Operator, Comma Separated Strings> [{ -h | --groups }] <Operator, Comma Separated Strings> [{ -a | --active }] { True | TRUE | true | t | 1 | False | FALSE | false | f | 0 } [{ -m | --metadata }] <Operator, Comma Separated Strings>
```

#### 5.2.3.1.iv Parameters

**-n or --name <TEXT>**

Specify the name of the project.

**-A or --accounting-policy <TEXT>**

Specifies the accounting policy for the project. It can be begin\_period, end-period or proportionate

**-S or --start-date <TEXT>**

Start date of the Project. Format: YYYY-MM-DD.

**-E or --end-date <TEXT>**

End date of the Project. Format: YYYY-MM-DD.

**-c or --clusters <Operator, Comma Separated Strings>**

You can link clusters using + operator and unlink clusters using - operator. For example:

*+cluster1,cluster2,cluster3... or -cluster4,cluster5,cluster6...*

**-u or --users <Operator, Comma Separated Strings>**

You can link users using + operator and unlink users using - operator. For example,

*+user1,user2,user3... or -user4,user5,user6...*

**-h or --groups <Operator, Comma Separated Strings>**

You can link groups using + operator or unlink users using - operator. For example,

*+group1,group2,group3... or -group4,group5,group6...*

**-m or --metadata <Operator, Comma Separated Strings>**

Add, Update, or Remove Metadata to or from the project account. The format can be

*+<key1>:<data1>,<key2>:<data2> or - <key1>,<key2>*

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the project to active/inactive.

Note: The + operation will add a new entity if it is not present or update an existing entry.

The - operator will remove an entry.

### 5.2.3.1.v Command Example

Add a new data 'currency:rupee' and update the existing data region as america:

```
amgr update project -n proj1 -m + currency:rupee,region:america
```

Remove the existing data type:

```
amgr update project -n proj1 -m - type,region
```

Multiple operations in single command:

```
amgr update project -n proj1 -m + currency:dollar,"Lead Researcher":"John Smith" -m - type,region
```

## 5.2.3.2 Updating Users

### 5.2.3.2.i Name

*amgr update user*

### 5.2.3.2.ii Description

Update the details of the user.

### 5.2.3.2.iii Syntax

```
amgr update user { -n | --name } TEXT [{ -A | --accounting-policy }] begin_period, end_period, proportionate [{ -S | --start-date }] [{ -E | --end-date }] [{ -c | --clusters }] <Operator, Comma Separated Strings> { -r | --roles } TEXT [{ -h | --groups }] <Operator, Comma Separated Strings> [{ -a | --active }] { True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }
```

### 5.2.3.2.iv Parameters

**-n or --name <TEXT>**

Specify the name of the user account.

**-A or --accounting-policy <TEXT>**

Specifies the accounting policy for the user account. It can be begin\_period, end-period or proportionate

**-S or --start-date <TEXT>**

Start date of the Project. Format: YYYY-MM-DD.

**-E or --end-date <TEXT>**

End date of the Project. Format: YYYY-MM-DD.

**-c or --clusters <Operator, Comma Separated Strings>**

You can link clusters using + operator and unlink clusters using - operator. For example,

**+cluster1,cluster2,cluster3... or -cluster4,cluster5,cluster6...**

**-r or --roles <TEXT>**

Set the role of the user. Users with Manager role can transfer funds to the user account.

**-h or --groups <Operator, Comma Separated Strings>**

You can link groups using + operator or unlink users using - operator. For example,

**+group1,group2,group3... or -group4,group5,group6...**

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the project to active/inactive.

### 5.2.3.3 Updating Groups

#### 5.2.3.3.i Name

*amgr update group*

#### 5.2.3.3.ii Description

Update the details of the group.

#### 5.2.3.3.iii Required Privilege

Only an administrator can update a group.

#### 5.2.3.3.iv Syntax

*amgr update group { -n | --name } TEXT { -i | --investors } TEXT { ,Àim | --managers } TEXT { -a | --active } TEXT*

#### 5.2.3.3.v Parameters

**-n or --name <TEXT>**

Specify the name of the budget group.

**-i or --investors <TEXT>**

Provide the name of the investor to link or unlink with the group.

**-m or --managers <TEXT>**

Provide the name of the manager to link or unlink with the group.

**-a or --active <TEXT>**

Specify whether the group is active or not.

### 5.2.3.4 Updating Clusters

#### 5.2.3.4.i Name

*amgr update cluster*

#### 5.2.3.4.ii Description

Update the details of the cluster.

#### 5.2.3.4.iii Syntax

*amgr update cluster { -n | --name } TEXT [{ -a | --active }] { True | TRUE | true | t | 1 | False | FALSE | false | f | 0 }*

### 5.2.3.4.iv Parameters

**-n or --name <TEXT>**

Specify the name of the Cluster. The cluster name should match the name of the PBS Server hostname. Multiple PBS Servers are supported.

**-a or --active [True|TRUE|true|t|1|False|FALSE|false|f|0]**

Set the Cluster active/inactive. It is set to active by default.

Note: All update commands are like add. Name of a record cannot be updated.

## 5.2.3.5 Updating Configurations

### 5.2.3.5.i Name

*amgr update config*

### 5.2.3.5.ii Description

Update Budget configurations.

### 5.2.3.5.iii Syntax

*amgr update config [{ -n | --name TEXT }] [{ -V | --config-value JSON\_STRING }]*

### 5.2.3.5.iv Parameters

**-n or --name <TEXT>**

Specify the name of the configuration attribute.

**-V or --config-value**

JSON formatted string of configuration values. Example:

**amgr update config -n SU\_DYNAMIC -V { data\_lifetime : 1000 }**

Note: As of now we have only one configuration attribute called `data_lifetime` for `SU_DYNAMIC` type of service units. The value of `data_lifetime` is specified in seconds. It is the time for which Budget will wait for an update to `SU_DYNAMIC` (Dynamic Service Unit). If the update does not happen within the specified time, a warning message will be logged in the Budget logs. Jobs are not blocked even if the `data_lifetime` is exceeded.

## 5.2.4 Removing Elements

The `amgr rm` commands have the same subcommands as the `amgr add` subcommands.

Note: The periods where transactions have happened cannot be removed. If projects, clusters, or service units are removed for periods where transactions are made, they are made inactive.

## 5.2.5 Getting Reports on Elements

The `amgr report` command allows you to get the reports for a projects, groups, transactions, and users.

Operates on entities: project, transaction, group, user.

Transactions are tracked over particular time frames, usually for a month, quarter or year. All transaction information is stored in a database allowing extensive statistical and allocation tracking. The reports of these transactions enable stakeholders to budget their resource usage. These reports are displayed as tables in the console and can be output as CSV files.

### 5.2.5.1 Getting Project Reports

#### 5.2.5.1.i Name

*amgr report project*

#### 5.2.5.1.ii Description

Provides project-level information in multiple formats.

#### 5.2.5.1.iii Syntax

```
amgr report project { -n | --name } TEXT { -s | --serviceunit } TEXT { -t | --sunit-type } TEXT { -U | --user-wise } TEXT {
 -h | --groups } TEXT { -p | --period } TEXT [{ -S | --start-date }] TEXT [{ -E | --end-date }] TEXT { -l | --list-info } [{
 -o | --out-file }] TEXT [{ -r | --raw-output }]
```

#### 5.2.5.1.iv Parameters

**-n or --name <TEXT>**

Specify the name of the Project.

**-n or --name <TEXT>**

Specify the name of the Project.

**-s or --serviceunit <TEXT>**

Service unit (name) for which user wants the report.

**-t or --sunit-type <TEXT>**

Specify service unit type, it can be one of the ('SU\_STANDARD', 'SU\_DYNAMIC'). Default is 'SU\_STANDARD'.

**-U or --user-wise <TEXT>**

User wise external updates that happened for dynamic service unit under the project.

**-h or --groups <TEXT>**

groups which are invested in the project and their invested amounts.

**-p or --period <TEXT>**

Period name (cannot be used with -S and -E options). Default is current period.

**-S or --start-date <TEXT>**

Start date from which user wants to see the report (cannot be used without -l or -g). It includes updated and created transactions from given date. Format: YYYY-MM-DD HH:MM:SS.

**-E or --end-date <TEXT>**

End date till which user wants to see the report (cannot be used without -l or -g). It includes updated and created transactions till date. Format: YYYY-MM-DD HH:MM:SS.

**-l or --list-info**

Detailed project report showing all transactions that have happened for the specified project.

**-o or --out-file <TEXT>**

Output file path.

**-r or --raw-output**

Show raw (CSV) output.

#### 5.2.5.1.v Output Format

Output for the report will contain the name, start\_date, end\_date, opening\_balance, total\_credits, total\_debits\_reconciled, total\_debits\_authorized and net\_balance in columns.

Use the -l switch to get the report for the project in long format which will contain the transaction\_id, transaction\_date, transaction\_time, entity, transaction\_type, transaction\_user, type amount and reconciled status in columns.

If you specify the -S --start date and -E --end date, the details for that time period will be displayed.

### 5.2.5.1.vi Command Example

- Report for all service units and current lowest period:

```
amgr report project -n p1
```

Command output:

```

name | period | serviceunit | opening_balance | total_credits

p1 | DEC-2018 | dollar1 | 0.0 | 3000000.0

| total_debits | total_debits_reconciled | total_debits_authorized

| 0.0 | 180.0 | 0.0

| net_balance

| 2999820.0
```

Example 5-1: Report for service unit dollar1 for period 2018:

```
amgr report project -n p1 -s dollar1 -p 2018
```

Command output:

```

name | period | serviceunit | opening_balance | total_credits

p1 | 2018 | dollar1 | 0.0 | 5000000.0

| total_debits | total_debits_reconciled | total_debits_authorized

| 0.0 | 0.0 | 0.0

| net_balance

| 5000000.0
```

Raw output of the above example:

```
amgr report project -n p1 -s dollar1 -p 2018 -r
```

Command output:

```
name,period,service-
unit,opening_balance,total_credits,total_debits,total_debits_reconciled,total_debits_authorized
,net_balance
p1,2018,dollar1,0.0,5000000.0,0.0,0.0,0.0,5000000.0
```

Example 5-2: Shows individual transactions for the service unit dollar1 for the lowest period.

```
amgr report project -n p1 -s dollar1 -l
```

Command output:

```

transaction_id | transaction_date | transaction_time | entity

1544096706.291656 | 2018-12-06 | 17:15:06.290064 | manager
2042.centos7 | 2018-12-06 | 17:15:23.760451 | job
2043.centos7 | 2018-12-06 | 17:15:24.695462 | job
2044.centos7 | 2018-12-06 | 17:16:24.058123 | job

| transaction_type | transaction_user | type | serviceunit | amount

| grant | sanketb | credit | dollar1 | 3000000.0
| acquired | pbsuser | debit | dollar1 | 60.0
| acquired | pbsuser | debit | dollar1 | 60.0
| acquired | pbsuser | debit | dollar1 | 60.0

| reconciled | period | comment

| yes | DEC-2018 | Deposit dollar1 to DEC period
| yes | DEC-2018 |
| yes | DEC-2018 |
| yes | DEC-2018 |
```

Example 5-3: Shows individual transactions for the service unit dollar1 for date range:

```
amgr report project -n p1 -s dollar1 -l -S '2018-12-06' -E '2018-12-06'
```

Command output:

transaction_id	transaction_date	transaction_time	entity
1544096706.100772	2018-12-06	17:15:06.098180	manager
1544096706.291656	2018-12-06	17:15:06.290064	manager
2042.centos7	2018-12-06	17:15:23.760451	job
2043.centos7	2018-12-06	17:15:24.695462	job
2044.centos7	2018-12-06	17:16:24.058123	job

transaction_type	transaction_user	type	serviceunit	amount
grant	sanketb	credit	dollar1	5000000.0
grant	sanketb	credit	dollar1	3000000.0
acquired	pbsuser	debit	dollar1	60.0
acquired	pbsuser	debit	dollar1	60.0
acquired	pbsuser	debit	dollar1	60.0

reconciled	period	comment
yes	2018	Deposit dollar1 to parent period
yes	DEC-2018	Deposit dollar1 to DEC period
yes	DEC-2018	
yes	DEC-2018	
yes	DEC-2018	

### 5.2.5.1.vii Report Formats for Dynamic Service Units (SU\_DYNAMIC)

- Project report in short format:  
`amgr report project -n p1 -t SU_DYNAMIC`

```

name | serviceunit | period | limit |

p1 | luster | 2020 | 500.0 |
p1 | scratch | 2020 | 800.0 |

```

```

last_reported_time | total_consumed

2020-04-07 12:40:22.470078+05:30 | 80
2020-04-07 12:40:22.470078+05:30 | 100

```

- Project report in user wise format:

```
amgr report project -n p1 -t SU_DYNAMIC -U
```

```

name | serviceunit | period | limit |

p1 | luster | 2020 | 500.0 |
p1 | scratch | 2020 | 800.0 |

```

```

last_reported_time | total_consumed | user_consumed

2020-04-07 12:40 | 80 | {"pbsuser": 20.0, "pbsuser1": 10.0}
2020-04-07 12:40 | 100 | {"pbsuser": 40.0}

```

- User report in short format:

```
amgr report user -n pbsuser -t SU_DYNAMIC
```

```

name | serviceunit | period | limit

pbsuser | luster | 2020 | 600.0
pbsuser | scratch | 2020 | 800.0

```

```

| last_reported_time | total_consumed

| 2020-04-07 12:40:22.470078+05:30 | 40
| 2020-04-07 12:40:22.470078+05:30 | 60

```

Note: User reports do not have user wise format.

## 5.2.5.2 Getting Group Reports

### 5.2.5.2.i Name

*amgr report group*

### 5.2.5.2.ii Description

Provides group report

### 5.2.5.2.iii Required Privilege

Note: Only an investor, a manager or an administrator can see the full report. This report will contain the deposits to the group and withdrawals from the group.

### 5.2.5.2.iv Syntax

```
amgr report group { -n | --name } TEXT { -h | --investors } TEXT { -A | --allocated-view } TEXT [{ -S | --start-date }]
TEXT [{ -E | --end-date }] TEXT { -l | --long-format } [{ -o | --out-file }] TEXT [{ -r | --raw-output }] [{ -p | --period
}] TEXT
```

### 5.2.5.2.v Parameters

-n or --name <TEXT>

Specify the name of the group.

-h or --investors <TEXT>

Specify investors. This will provide list of investors linked to the group and their investments.

-A or --allocated-view <TEXT>

This will provide a break up how much the group has invested in project or user accounts.

-S or --start-date <TEXT>

Start date from which user wants to see the report (cannot be used without -l). Format: %Y-%m-%d

-E or --end-date <TEXT>

End date till which user wants to see the report (cannot be used without -l). Format: %Y-%m-%d.

-l or --long-format

Detailed report of transactions performed by the specified group.

-o or --out-file <TEXT>

- Output file path.

-r or --raw-output

- Show raw (csv) output.

-p or --period-name <TEXT>

- Period name (cannot be used with -S and -E options). Default is current period.

### 5.2.5.2.vi Group Report Formats

- General group report:

```
amgr report group -n h1
```

Command output:

```

name | serviceunit | opening_balance | total_credits | total_debits

h1 | cpu_hrs | 0.0 | 100000.0 | 100.0

| total_allocated | total_accounts_released | net_balance

| 600.0 | 70.0 | 99370.0

```

- Long format group report:

**amgr report group -n h1 -l**

Command output:

```

transaction_id | transaction_date | transaction_time | entity | transaction_type

1570782001.2559264 | 2019-10-11 | 13:50:01.253271 | investor | grant
2470123401.5592132 | 2019-10-11 | 13:50:11.967594 | manager | grant
6470127408.2212197 | 2019-10-11 | 13:50:31.161543 | manager | grant

```

```

transaction_user | type | serviceunit | amount | balance | period | account

root | credit | cpu_hrs | 500000.0 | 500000.0 | - | group1
mgr1 | credit | cpu_hrs | 1000.0 | 499996.0 | 2019 | Project1
mgr2 | credit | cpu_hrs | 4.0 | 499992.0 | 2019 | User1

```

- Investor format report:

**amgr report group -n h1 -h**

Command output:

```

investor | serviceunit | balance

root | cpu_hrs | 50000.0
rsv | cpu_hrs | 50000.0

```

- Report for primary group accounts:

**amgr report user -n h1 -h**

Command output:

```

group | period | serviceunit | balance

h1 | 2019 | cpu_hrs | 1500.0
h2 | 2019 | cpu_hrs | 1500.0

```

- Investor format report for groups:

This report is meant to show the user where the managers have deposited the group's currency.

```
amgr report group -n h1 -A
```

Command output:

```

account | period | serviceunit | balance

root | 2019 | cpu_hrs | 498976.0
rsv | 2019 | cpu_hrs | 498975.0

```

### 5.2.5.3 Getting Transaction Reports

#### 5.2.5.3.i Name

*amgr report transaction*

#### 5.2.5.3.ii Description

#### 5.2.5.3.iii Syntax

```
amgr report transaction { -i | --transaction-id } TEXT { -l | --list-info } { -N | --nonreconcile } TEXT [{ -o | --out-file }]
TEXT [{ -r | --raw-output }]
```

#### 5.2.5.3.iv Parameters

**-i or --transaction-id <TEXT>**

Specify job ID.

**-l or --list-info**

Detailed transaction report showing all entries of specified transaction ID.

**-N or --non-reconcile**

Show all non-reconciled transactions having reconcile count  $\geq$  value. e.g. `amgr report transaction -N 3` will display all non-reconciled transactions with `reconcile_count  $\geq$  3`.

Transactions with `reconcile_count  $\geq$  3` have to be reconciled manually using the `amgr reconcile <project>/<user>` command. By default, Budget will attempt to reconcile a job three times and then mark the job as non-reconciled.

**-o or --out-file <TEXT>**

Output file path.

**-r or --raw-output**

Show raw (csv) output.

#### 5.2.5.3.v Output Format

Output for the report will contain the `transaction_id`, `project`, `user_name`, `reconciled_service_units` in columns.

Note: If a job is not reconciled, it will appear only -l long format report.

Use the -l switch to get the report for the transaction in long format which will contain the `transaction_id`, `transaction_date`, `transaction_time`, `project`, `transaction_type`, credit or debit, service units and amounts.

#### 5.2.5.3.vi Command Example

- Getting job report:

```
amgr report transaction -i 2044.centos7
```

Command output:

```

transaction | account | user | reconciled_dollar1

```

```
2044.centos7 | p1 | pbsuser | 60.0
```

```

| reconciled_dollar2

```

```
| 21120.0
```

- Long format for job information showing individual transactions:

```
amgr report transaction -i 2044.centos7 -l
```

Command output:

```

transaction_id | transaction_date | transaction_time | account

```

```
2044.centos7 | 2018-12-06 | 17:17:46.655998 | p1
```

```
2044.centos7 | 2018-12-06 | 17:16:24.058123 | p1
```

```
2044.centos7 | 2018-12-06 | 17:16:24.058123 | p1
```

```

| transaction_type | type | service_unit

```

```
| acquired | debit | dollar2
```

```
| acquired | debit | dollar2
```

```
| acquired | debit | dollar1
```

```

| amount | period | comment

```

```
| 19920.0 | DEC-2018 | overrun:
```

```
| 1200.0 | DEC-2018 |
```

```
| 60.0 | DEC-2018 |
```

## 5.2.5.4 Getting User Reports

### 5.2.5.4.i Name

*amgr report user*

### 5.2.5.4.ii Description

### 5.2.5.4.iii Syntax

```
amgr report user { -n | --name } TEXT { -s | --serviceunit TEXT | { -t | --sunit-type } TEXT } { -h | --groups } TEXT { -p | --period TEXT } [{ -S | --start-date }] TEXT [{ -E | --end-date }] TEXT { -l | --list-info } [{ -o | --out-file }] TEXT [{ -r | --raw-output }]
```

### 5.2.5.4.iv Parameters

**-n or --name <TEXT>**

Specify the name of the user.

**-s or --serviceunit <TEXT>**

Serviceunit for which user wants the report.

**-t or --sunit-type <TEXT>**

Specify service unit type, it can be one of the ('SU\_STANDARD', 'SU\_DYNAMIC'). Default is 'SU\_STANDARD'.

**-h or --groups <TEXT>**

groups which are invested in the user account and their invested amounts.

**-p or --period <TEXT>**

Period name(cannot be used with -S and -E options). Default is current period

**-S or --start-date <TEXT>**

Start date from which user wants to see the report(cannot be used without -l or -g). It includes updated and created transactions from given date. Format: YYYY-MM-DD HH:MM:SS.

**-E or --end-date <TEXT>**

End date till which user wants to see the report (cannot be used without -l or -g). It includes updated and created transactions till date. Format: YYYY-MM-DD HH:MM:SS.

**-l or --list-info**

Detailed user account report showing all transactions that have happened for the specified user.

**-o or --out-file <TEXT>**

Output file path.

**-r or --raw-output**

Show raw (CSV) output.

### 5.2.5.4.v Output Format

Output for the report contains the Name, Service unit, Period, Opening Balance, Total Credits, Total Debits, Total Debits (Reconciled), Total Debits (Authorized), Net Balance

Opening Balance

Opening balance of user account as on start date provided

Total Credits

Sum of deposits and release of blocker budget between given duration

Total Debits (Reconciled)

Total consumed amount.

Total Debits (Authorized)

Jobs which are holding amount (running jobs) and finished which are not reconciled still.

Current balance

Opening Balance + Total Credits - Total Debits - Total Debits(Reconciled) - Total Debits(Authorized)

### 5.2.5.4.vi Command Example

Detailed user (account) report (long listing requested):

```
amgr report user -n <username> -s <serviceunit> -S <startdate> -E <enddate> -l
```

## 5.3 Commands for Managing Service Units

The Budget service units commands allow you to deposit, check available, withdraw, precheck, acquire, reconcile, refund, and transfer service units.

The maximum amount of service units an account can hold is 999999999999.99.

The service units commands have subcommands for user and project entities.

These commands are used internally by the job hook and are available for programmatic usage:

- **precheck** - Before job is queued.  
Precheck validates if the job is ready for queuing. If the precheck fails, the job is not queued.
- **acquire** - Before job runs  
Acquire is run after precheck and fetches the required service units when the job runs.
- **reconcile** - After job finishes  
Reconcile is run after the job has finished running and returns the balance service units to the account.

After the budget allocated to an account is exhausted, the balance is not allowed to become negative; in this case jobs are no longer dispatched to run.

If the license server is not reachable, the jobs will continue to run for a period of 3 hours till the connection is established.

Note: For Array Jobs, reconciliation fails for the first index subjob in PBS Professional versions older than 19.2.1. To workaround this issue, the admin can manually reconcile the first index sub job for the submitted job array.

Note: When a job fails and the epilogue hook event times out without making an accounting entry, the admin can manually reconcile the job with the correct information.

The Budget Service Units commands and their respective subcommands are as follows:

**Table 5-4: Budget Service Units Commands**

Function	Command	Subcommands
Deposit Service units	<code>amgr deposit</code>	<code>user, project, group</code>
Check Balance Service Units	<code>amgr checkbalance</code>	<code>user, project, group</code>
Withdraw Service Units	<code>amgr withdraw</code>	<code>user, project, group</code>
Transfer Service Units	<code>amgr transfer</code>	<code>user, project, group</code>
Precheck Service Units Balance	<code>amgr precheck</code>	<code>user, project</code>
Acquire Service Units	<code>amgr acquire</code>	<code>user, project</code>
Reconcile Service Units	<code>amgr reconcile</code>	<code>user, project</code>
Refund Service Units	<code>amgr refund</code>	<code>user, project</code>

### 5.3.1 Depositing Service Units

*amgr deposit*

Operates on entities: user, project and group

### 5.3.1.1 Depositing Service Units to Project

#### 5.3.1.1.i Name

*amgr deposit project*

#### 5.3.1.1.ii Description

Deposit service units to a project.

#### 5.3.1.1.iii Syntax

*amgr deposit project { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -p | --period } TEXT { -h | --group } TEXT [{ -C | --comment }] TEXT*

#### 5.3.1.1.iv Parameters

-n or --name <TEXT>

Specify the name of the Project.

-s or --serviceunits <TEXT FLOAT>

Specify the service units associated with the Project account and the quantity for deposit.

-p or --period <TEXT>

Specify the name of the period.

-h or --group <TEXT>

Specify the name of the groups to allocate budget from.

-C or --comment <TEXT>

Provide a comment/reason for the deposit. Default is None.

### 5.3.1.2 Deposit Service Units to User Account

#### 5.3.1.2.i Name

*amgr deposit user*

#### 5.3.1.2.ii Description

Deposit service units to a user account.

#### 5.3.1.2.iii Syntax

*amgr deposit user | { -n | --name } TEXT | { -s | --serviceunits } TEXT FLOAT | { -p | --period } TEXT | { -h | --group } TEXT | [{ -C | --comment }] TEXT*

#### 5.3.1.2.iv Parameters

-n or --name <TEXT>

Specify the name of the user account.

-s or --serviceunits <TEXT FLOAT>

Specify the service units associated with the user account and the quantity for deposit. e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

-p or --period <TEXT>

Specify the name of the period.

-h or --group <TEXT>

Specify the name of the groups to allocate budget from.

-C or --comment <TEXT>

Provide a comment/reason for the deposit. Default is None.

### 5.3.1.3 Depositing Service Units to Group

#### 5.3.1.3.i Name

*amgr deposit group*

#### 5.3.1.3.ii Description

Deposit service units to a group.

#### 5.3.1.3.iii Syntax

*amgr deposit group { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -C | --comment } TEXT*

#### 5.3.1.3.iv Parameters

-n or --name <TEXT>

Specify the name of the group.

-s or --serviceunits <TEXT FLOAT>

Specify the service units associated with the group and the quantity for deposit.e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

-C or --comment <TEXT>

Provide a comment/reason for the deposit. Default is none.

## 5.3.2 Checking Service Unit Balance

*amgr checkbalance*

Operates on entities: user, project, group

### 5.3.2.1 Checking Service Unit Balance for Project

#### 5.3.2.1.i Name

*amgr checkbalance project*

#### 5.3.2.1.ii Description

Get available budget for a project.

#### 5.3.2.1.iii Syntax

*amgr checkbalance project { -n | --name } TEXT { -p | --period } TEXT*

#### 5.3.2.1.iv Parameters

-n or --name <TEXT>

Specify the name of the Project.

-p or --period <TEXT>

Specify the name of the period.

**5.3.2.1.v Output**

```
{'<STANDARD_UNIT_1>': <value>,
<STANDARD_UNIT_2>: <value>,
<DYNAMIC_UNIT_1>: {'used': <value>, 'limit': <value>},
<DYNAMIC_UNIT_2>: {'used': <value>, 'limit': <value>}}
```

**5.3.2.1.vi Command Example**

```
{'luster': {'used': 0.0, 'limit': 300}, 'cpu_hrs': 0.0, 'gpu_hrs': 0.0}
```

**5.3.2.2 Checking Service Unit Balance for User****5.3.2.2.i Name**

*amgr checkbalance user*

**5.3.2.2.ii Description**

Get available budget for a user account.

**5.3.2.2.iii Syntax**

*amgr checkbalance user { -n | --name } TEXT { -p | --period } TEXT*

**5.3.2.2.iv Parameters**

-n or --name <TEXT>

Specify the name of the user account.

-p or --period <TEXT>

Specify the name of the period.

**5.3.2.3 Checking Service Unit Balance for Group****5.3.2.3.i Name**

*amgr checkbalance group*

**5.3.2.3.ii Description**

Get available budget for a group.

**5.3.2.3.iii Syntax**

*amgr checkbalance group { -n | --name } TEXT*

**5.3.2.3.iv Parameters**

-n or --name <TEXT>

Specify the name of the group.

**5.3.3 Withdrawing Service Units**

Withdraws service units from entity.

*amgr withdraw*

Operates on entities: user, project, group

### 5.3.3.1 Withdrawing Service Units from Project

#### 5.3.3.1.i Name

*amgr withdraw project*

#### 5.3.3.1.ii Description

Withdraw service units from a project.

#### 5.3.3.1.iii Required Privilege

Only Managers can run this command. Managers can only withdraw according to their shares.

#### 5.3.3.1.iv Syntax

```
amgr withdraw project { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -p | --period } TEXT { -h | --group }
TEXT [{ -C | --comment }] TEXT
```

#### 5.3.3.1.v Parameters

-n or --name <TEXT>

Specify the name of the Project.

-S or --serviceunits <TEXT FLOAT>

Specify the service units associated with the Project account and the quantity to withdraw.e.g.”-s cpu\_hrs 100”  
or “-s cpu\_hrs 100.0”

-p or --period <TEXT>

Specify the name of the period.

-h or --group <TEXT>

Specify the group to allocate to.

-C or --comment <TEXT>

Provide a comment/reason for the deposit. Default is None.

### 5.3.3.2 Withdrawing Service Units from User

#### 5.3.3.2.i Name

*amgr withdraw user*

#### 5.3.3.2.ii Description

Withdraw service units from a user account.

#### 5.3.3.2.iii Required Privilege

Note: Only a manager can run this command. Managers can withdraw only according to their shares. The budget withdrawn will go back to the same pool it was deposited from.

#### 5.3.3.2.iv Syntax

```
amgr withdraw user { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -p | --period } TEXT { -h | --group } TEXT
[{ -C | --comment }] TEXT
```

#### 5.3.3.2.v Parameters

-n or --name <TEXT>

Specify the name of the user account.

**-S or --serviceunits <TEXT FLOAT>**

Specify the service units associated with the user account and the quantity to withdraw. e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

**-p or --period <TEXT>**

Specify the name of the period.

**-h or --group <TEXT>**

Specify the group to allocate to.

**-C or --comment <TEXT>**

Provide a comment/reason for the deposit. Default is None.

### 5.3.3.3 Withdrawing Service Units from Group

#### 5.3.3.3.i Name

*amgr withdraw group*

#### 5.3.3.3.ii Description

Withdraw service units from a group.

#### 5.3.3.3.iii Required Privilege

Note: Only investors can run this command. Investor can only withdraw their own share.

#### 5.3.3.3.iv Syntax

*amgr withdraw group { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT [{ -C | --comment }] TEXT*

#### 5.3.3.3.v Parameters

**-n or --name <TEXT>**

Specify the name of the group.

**-S or --serviceunits <TEXT FLOAT>**

Specify the service units and the quantity to withdraw.e.g.”-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

**-C or --comment <TEXT>**

Provide a comment/reason for the deposit. Default is None.

## 5.3.4 Prechecking Service Units Balance

*amgr precheck*

Find out whether we can run a job at a specified date on a cluster for a duration for a specific amount of service units. If this command returns False, the job cannot be run; this means the budget is insufficient, the cluster is not available, etc.

Operates on entities: user, project

### 5.3.4.1 Prechecking a Project

#### 5.3.4.1.i Name

*amgr precheck project*

**5.3.4.1.ii Description****5.3.4.1.iii Syntax**

*amgr precheck project { -n | --name } TEXT { -c | --cluster } TEXT { -D | --transactiondate } TEXT { -d | --duration } INTEGER { -s | --serviceunits } TEXT FLOAT*

**5.3.4.1.iv Parameters**

-n or --name <TEXT>

Specify the name of the Project.

-c or --cluster <TEXT>

Specify the cluster.

-D or --transaction-date <TEXT>

Specify the transaction date and time. Format: YYYY-MM-DD

-d or --duration <INTEGER>

Specify the duration (in seconds).

-s or --serviceunits <TEXT, FLOAT>

Specify the service units and required budget.

**5.3.5 Acquiring Service Units**

*amgr acquire*

Fetches the service units required to run a job. Run the precheck command first to make sure there are enough service units available.

Operates on entities: user, project.

**5.3.5.0.i Required Privilege**

Acquire and Reconcile commands can be run only by admin users.

**5.3.5.1 Acquiring Service Units for Project****5.3.5.1.i Name**

*amgr acquire project*

**5.3.5.1.ii Description****5.3.5.1.iii Syntax**

*amgr acquire project { -n | --name } TEXT { -c | --cluster } TEXT { -s | --serviceunits } TEXT FLOAT { -D | --transaction-date } TEXT { -i | --transaction-id } TEXT { -d | --duration } { -u | --user } INTEGER [{ -C | --comment }] TEXT { -R | --run-count } INTEGER*

**5.3.5.1.iv Parameters**

-n or --name <TEXT>

Specify the name of the Project.

-c or --cluster <TEXT>

Specify the cluster.

**-s or --serviceunits <TEXT FLOAT>**

Specify the service units and required budget. Example: “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”.

**-D or --transaction-date <TEXT>**

Specify the transaction date and time. Format: YYYY-MM-DD HH:MM:SS

**-i or --transaction-id <TEXT>**

Specify the transaction ID.

**-d or --duration <INTEGER>**

Specify the duration (in seconds).

**-u or --user <TEXT>**

Specify the user for whom acquire has to be done.

**-C or --comment <TEXT>**

Provide a comment/reason for the acquire. Default is None.

**-R or --run-count <INTEGER>**

Specify the run count for the transaction.

### 5.3.5.2 Acquiring Service Units for User

#### 5.3.5.2.i Name

*amgr acquire user*

#### 5.3.5.2.ii Description

The teller uses this command to acquire service units for a user.

#### 5.3.5.2.iii Syntax

*amgr acquire user { -n | --name } TEXT { -c | --cluster } TEXT { -s | --serviceunits } TEXT FLOAT { -D | --transaction-date } TEXT { -i | --transaction-id } TEXT { -d | --duration } { -u | --user } INTEGER [{ -C | --comment } ] TEXT { -R | --run-count } INTEGER*

#### 5.3.5.2.iv Parameters

**-n or --name <TEXT>**

Specify the name of the User.

**-c or --cluster <TEXT>**

Specify the cluster.

**-s or --serviceunits <TEXT FLOAT>**

Specify the service units and required budget. Example: “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”.

**-D or --transaction-date <TEXT>**

Specify the transaction date and time. Format: YYYY-MM-DD HH:MM:SS

**-i or --transaction-id <TEXT>**

Specify the transaction ID.

**-d or --duration <INTEGER>**

Specify the duration (in seconds).

**-u or --user <TEXT>**

Specify the user for whom acquire has to be done.

**-C or --comment <TEXT>**

Provide a comment/reason for the acquire. Default is None.

**-R or --run-count <INTEGER>**

Specify the run count for the transaction.

## 5.3.6 Reconciling Service Units

Reconciles service units

*amgr reconcile*

Reconcile is run after the job is completed and returns excess service units back to the account.

The following are the subcommands available: user, project.

### 5.3.6.1 Reconciling Service Units for Project

#### 5.3.6.1.i Name

*amgr reconcile project*

#### 5.3.6.1.ii Description

Reconciles service units when job has finished. Removes consumed service units from escrow, and returns unused service units.

#### 5.3.6.1.iii Required Privilege

Note: Acquire and Reconcile commands can be run only by admin users.

#### 5.3.6.1.iv Syntax

*amgr reconcile project { -n | --name } TEXT { -c | --cluster } TEXT { -s | --serviceunits } TEXT FLOAT { -D | --transaction-date } TEXT { -i | --transaction-id } TEXT { -d | --duration } INTEGER [{ -C | --comment } ] TEXT*

#### 5.3.6.1.v Parameters

**-n or --name <TEXT>**

Specify the name of the Project.

**-c or --cluster <TEXT>**

Specify the cluster.

**-s or --serviceunits <TEXT FLOAT>**

Specify the service units and required budget. Example: “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

**-D or --transaction-date <TEXT>**

Specify the transaction date and time. Format: YYYY-MM-DD HH:MM:SS

**-i or --transaction-id <TEXT>**

Specify the transaction ID.

**-d or --duration <INTEGER>**

Specify the duration (in seconds).

**-u or --user <INTEGER>**

Specify the user for whom reconcile has to be done.

**-C or --comment <TEXT>**

Provide a comment/reason for the deposit. Default is None.

Note: The service units amount should be the exact service units consumed by the job.

## 5.3.6.2 Reconciling Service Units for Job

### 5.3.6.2.i Name

*amgr reconcile job*

### 5.3.6.2.ii Description

Reconcile PBS jobs.

Note: This command has to be run on a machine where PBS server is present and it must be run as a root user.

### 5.3.6.2.iii Syntax

*amgr reconcile job { -i | --transaction-ids } TEXT { --all } { -u | --teller-user } TEXT*

### 5.3.6.2.iv Parameters

**-i or --transaction-ids <TEXT>**

String of comma separated job ids (same as transaction ids). Example:

`"<jobid1>,<jobid2>,<jobid3>"`

**--all**

Reconcile all non-reconciled jobs.

**-u or --teller-user <TEXT>**

Teller username (required)

This command has to be executed as the pbsadmin user. If you get a message asking you to log in and execute the command, you can do so for example, using the command `sudo -u <teller_user> <AM_EXEC>/bin/amgr sshlogin`

## 5.3.7 Refunding Service Units

Refunds service units for a specific transaction to the account of a project or user.

*amgr refund*

The Budget administrator can refund partial or full amounts (service units) to the account of a project or user. The administrator can choose to provide a refund for scenarios where a job fails or runs multiple times for reasons which cannot be attributed to the user.

Only Administrators are authorized to provide refunds.

Refunds can be done for active and inactive projects and users.

Multiple refunds are allowed. The total refund amount cannot exceed the total amount consumed by the job.

The refund amount will be for all service units consumed by the transaction ID.

The refund amount is calculated based on the percentage specified, applied to total consumed amount. Total consumed amount is the sum of all transaction amounts of all transaction runs for a transaction ID.

### 5.3.7.0.i Syntax

*amgr refund transaction { -i | --transactionID } TEXT { -r | --refund-percentage } Number { -p | --period-name } TEXT [{ -C | --comment } ] TEXT*

### 5.3.7.0.ii Parameters

- i or --transactionID <TEXT>  
Specify the name of the transaction.
- r or --refund-percentage <TEXT>  
Specify the refund percentage, a value between 1 and 100.
- p or --period-name <TEXT>  
Specify the period. If not mentioned, current period is taken.
- C or --comment <TEXT>  
Specify the remarks or comments providing the reason for refund.

## 5.3.8 Transferring Service Units

When an investor is unlinked from a group or a group is unlinked from a project, some service units may remain unclaimed and become unusable. The administrator can take ownership of these unclaimed amounts and transfer it back into the budget pool to make it usable again.

The Administrator can transfer service units:

- between two groups in a project
- between two projects (same or different group)
- between two investors in a group
- between two groups (same or different investors)
- between two groups in a user
- between two users (same or different groups)

*amgr transfer*

Operates on entities: project, user, group

### 5.3.8.1 Transferring Service Units for Project

#### 5.3.8.1.i Name

*amgr transfer project*

#### 5.3.8.1.ii Description

Transfer service units from one group to another group (within a project or between projects)

#### 5.3.8.1.iii Syntax

```
amgr transfer project { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -p | --period } TEXT { -F | --from-group } TEXT { -T | --to-group } TEXT { -P | --dest-project } TEXT { -C | --comment } TEXT
```

#### 5.3.8.1.iv Parameters

- n or --name <TEXT>  
Specify the name of the project.
- s or --serviceunits <TEXT FLOAT>  
Specify the service units and the amount. e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”
- p or --period <TEXT>  
Specify the period.

-F or --from-group <TEXT>

Specify from group.

-T or --to-group <TEXT>

Specify to group.

-P or --dest-project <TEXT>

Specify the destination project. Do not use in case transfer within same project.

-C or --name <TEXT>

Provide a comment/reason for the transfer.

## 5.3.8.2 Transferring Service Units for User

### 5.3.8.2.i Name

*amgr transfer user*

### 5.3.8.2.ii Description

Transfer service units from one group to another group (within a user account or between user accounts)

### 5.3.8.2.iii Syntax

*amgr transfer user { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -p | --period } TEXT { -F | --from-group } TEXT { -T | --to-group } TEXT { -U | --dest-user } TEXT { -C | --comment } TEXT*

### 5.3.8.2.iv Parameters

-n or --name <TEXT>

Specify the name of the user.

-s or --serviceunits <TEXT FLOAT>

Specify the service units and the amount. e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

-p or --period <TEXT>

Specify the period.

-F or --from-group <TEXT>

Specify from group.

-T or --to-group <TEXT>

Specify to group.

-U or --dest-user <TEXT>

Specify the destination user account. Do not use in case of transfer within same user account.

-C or --name <TEXT>

Provide a comment/reason for the transfer.

## 5.3.8.3 Transferring Service Units for Group

### 5.3.8.3.i Name

*amgr transfer group*

### 5.3.8.3.ii Description

Transfer service units from one investor to another investor (within a group or between groups)

**5.3.8.3.iii Syntax**

*amgr transfer group { -n | --name } TEXT { -s | --serviceunits } TEXT FLOAT { -F | --from-investor } TEXT { -T | --to-investor } TEXT { -G | --dest-group } TEXT { -C | --comment } TEXT*

**5.3.8.3.iv Parameters**

**-n or --name <TEXT>**

Specify the name of the group.

**-s or --serviceunits <TEXT FLOAT>**

Specify the service units and the amount. e.g. “-s cpu\_hrs 100” or “-s cpu\_hrs 100.0”

**-F or --from-investor <TEXT>**

Specify from investor.

**-T or --to-investor <TEXT>**

Specify to investor.

**-G or --dest-group <TEXT>**

Specify the destination group. Do not use in case of transfer within group.

**-C or --comment <TEXT>**

Provide a comment/reason for the transfer.

# Tutorial on Using Budget

## 6.1 Getting Started with Budget Commands

Here is a tutorial to help you get started with the Budget commands.

In this tutorial, we will be using the commands to create entities, submit jobs, check balance and view the service unit transactions. This can be used as a starting point to further explore the features of the application.

## 6.2 Getting Started with Budget Commands

Simple tutorial to help you get started with the Budget commands.

In this tutorial, we will be using the commands to create entities, submit jobs, check balance, and view the service unit transactions. This can be used as a starting point to further explore this feature.

To set up a scenario, follow the steps:

1. Create a period representing the year 2020.  
`amgr add period -n 2020 -S 2020-01-01 -E 2020-12-31`
2. Create a child period that represents the fourth quarter of the year 2020.  
`amgr add period -n 2020.Q4 -S 2020-10-01 -E 2020-12-31 -p 2020`
3. Add a PBS Server as a cluster.  
`amgr add cluster -n pbsserver`
4. Update the cluster by deactivating and activating it.  
`amgr update cluster -n pbsserver -a False`
5. To view the deactivated cluster, type:  
`amgr ls cluster -a False`
6. Let's update the cluster by activating it.  
`amgr update cluster -n pbsserver -a True`
7. To view the cluster, type  
`amgr ls cluster`
8. Create the service unit.

---

Ensure that the name matches the service unit configured in the formulas section of the `am_hook.json` configuration file

```
amgr add serviceunit -n cpu_hrs -d "CPU Hours"
```

9. Create a group named `test_group` with manager `pbsadmin` and investor `test_investor`.

```
amgr add group -n test_group -M pbsadmin -I test_investor
```

10. Create a project named `P1` with accounting policy `begin_period`, cluster `pbsserver`, user `pbsadmin` and group `root`.

```
amgr add project -n P1 -A begin_period -c pbsserver -u pbsadmin -h test_group
```

11. Add a user named "joe" who exists on your local machine

```
amgr add user -n joe -A begin_period -c pbsserver -r manager -h test_group
```

12. Deposit a budget of 120 CPU-hours to the `P1` project for the period `2020.Q4`

```
amgr deposit project -n P1 -s cpu_hrs 120.00 -p 2020.Q4
```

13. Check the balance of the `P1` Project

```
amgr checkbalance project -n P1 -p 2020.Q4
```

14. Withdraw 20 CPU-hours from the `P1` project for the period `2020.Q4`

```
amgr withdraw project -n P1 -s cpu_hrs 20.00 -p 2020.Q4
```

15. Run a sleep job for Project `2020.Q4` for 10 seconds with walltime of 2 minutes

```
qsub -P P1 -lwalltime=00:02:00 --/bin/sleep 10
```

-P specifies which project is charged. If omitted, the user account will be charged.

The job must have balance in the project or user account. The job must also specify a walltime; this walltime can be inherited from the server or queue.

16. You can check PBS Server logs with

```
vi /var/spool/pbs/server_logs/<yyyy:mm:dd>
```

17. To see the job running.

```
qstat -sw
```

18. Check the balance. It must have decreased by a large amount.

```
amgr checkbalance project -n P1 -p 2020.Q4
```

Once the job is finished, check the balance again and the unused amount will be reconciled.

19. Rerun a job.

```
qrerun jobid
```

When the job reruns, the amount acquired for running job will be released and the whole amount will be acquired again. Before next run the previous run usage will be reconciled and full amount will be acquired again.

Once the job completes the amount will be reconciled.

If a job is terminated with `qdel`, the acquired amount will be reconciled.

Note: If the job is terminated with `qdel -Wforce`, the amount has to be reconciled manually using helper commands or scripts since the accounting information is not provided to Budget by PBS Professional.

If a MoM fails, the job will get requeued and the amount will be acquired twice. Before the next run, Budget will reconcile the previous run. If unable to rerun, the job will be queued.

---

## 6.3 Submitting Jobs with Budget

To submit a job as an individual user, you need your own funds.

To submit a job as part of a project, you have to submit the job using the “-P” argument in `qsub`.

Groups can have multiple projects, and projects can have multiple groups; it's only user and project credit that counts when submitting a job.

# Installing Simulate

## 1.1 Supported Platforms for Simulate

- RHEL 7
- SLES 12

## 1.2 Prerequisites

- Altair License Manager 14.5+
- PBSProNodes or PBSProSockets 20.0 License Feature

## 1.3 Where to Install Simulate

You can install Simulate on any host that can reach the Altair License Manager. We recommend not installing it on the PBS server host, to avoid slowing that host.

For information about PBS Professional, see the *PBS Professional Administrator's Guide*.

## 1.4 Installation

1. Untar the Simulate package:  

```
tar xvfz PBSPro-sim_2020.1.0-RHEL7_x86_64.tar.gz
```
2. Change directory:  

```
cd PBSPro-sim_2020.1.0
```

## 1.5 Configuration

### 1.5.1 Configure Licensing for Simulate

The Simulate configuration file is named `sim.conf` and is in the installation directory.

In this file, edit the licensing parameter, and set it to `<port>@<license server host>`:

```
SIM_LICENSE_LOCATION=6200@<license server>
```

For example:

```
SIM_LICENSE_LOCATION=6200@mylicensehost
```

## 1.5.2 Set Path to Snapshot Directory

Optionally, if you want to, you can set the `PBS_SNAPSHOT_PATH` parameter in `sim.conf` to be the path to the snapshot directory. If you are working repeatedly on the same snapshot, this can make your command execution easier.

## 1.6 Setting Up User Environment

Set up your environment to point to the `simsh` wrapper command for simulator:

```
export PATH=/<your_install_path>/PBSPro-sim_2020.1.0:$PATH
```

# Using Simulate

## 2.1 Introduction

Simulate is useful for seeing the order in which jobs will run, and whether jobs will run, based on a snapshot taken from a working PBS complex. You can use this information to tune your PBS Professional configuration and change the workload behavior in order to meet your site's objectives.

## 2.2 Simulate Commands

### 2.2.1 The simsh Wrapper Script

*simsh* <path to snapshot> <command to execute> [command options]

*simsh* <path to snapshot> *sim* [sim options]

Command to execute for manipulating snapshots: *qmgr*, *qstat*, *qsub*, *pbsnodes*, *qdel*, *qselect*, *pbsfs*, *pbs\_rstat*, *pbs\_rsub*

Option for running simulations: *sim*

Other options: *--help*, *--version*

### 2.2.2 Options to the sim Command

*-o* <output path>

Path to output snapshot (default: <path to input snapshot>\_out)

*-t* <duration>

Time in seconds to to run simulated universe. Actual time required is much shorter. When used with the *-n* <cycles> option, simulation runs for the shorter time. For example, if you specify “*-t 600 -n 2*” and it only takes 30 seconds to run two scheduling cycles, the simulation ends after 30 seconds.

*-h*, *--help*

Display this help message

*-l*

Generate simulation log

*-L*

Generate scheduling logs

*-n* <cycles>

Number of scheduling cycles to run. When used with the *-t* <duration> option, simulation runs for the shorter time. For example, if you specify “*-t 600 -n 2*” and it only takes 30 seconds to run two scheduling cycles, the simulation ends after 30 seconds.

*--version*

Print the version of this command

---

`--monitor=<duration>`

Update the snapshot after every period specified by *duration*

`--OO`

Turn optimizations off

## 2.2.3 Command Examples

To get server information:

```
simsh <path to snapshot> qstat -Bf
```

To list all nodes:

```
simsh <path to snapshot> qmgr -c "list node @default"
```

To run a simulation for 10 cycles and generate scheduling logs:

```
simsh <path to snapshot> sim -L -n 10
```

To list all vnodes:

```
simsh <path to snapshot> pbsnodes -av
```

## 2.2.4 Command Paths

Many Simulate commands have the same names as PBS commands. The wrapper script `simsh` prevents naming clashes.

# 2.3 Using Simulate on a Snapshot

Overview:

- Get a snapshot from a running PBS Professional complex
- Check snapshot contents
- Run Simulate on the snapshot
- Review your results
- Modify your snapshot
- Run a simulation on your modified snapshot

## 2.3.1 Creating a Snapshot

This should be done on a system with queued workload. Simulate is useful for seeing what order jobs will run in and if they will run based on a “now” status taken from a working PBS complex:

```
pbs_snapshot --basic -o <output_path>
```

Note: A tar archive will be created in this folder.

Unpack the snapshot:

```
tar xvfz <snapshot_name>.tgz (e.g. tar xvfz snapshot_20200708_15_54_57.tgz)
```

## 2.3.2 Checking Snapshot Contents

To use `qstat` to inspect the contents of a snapshot:

```
simsh <snapshot_directory_name> qstat -asl
```

For example:

```
simsh snapshot_20200708_15_54_57 qstat -asl
```

Try the different `qstat` options; many are available. ( `-f` is not available on a snapshot.)

To use `qmgr`:

```
simsh <snapshot_directory_name> qmgr
```

For example:

```
simsh snapshot_20200708_15_54_57 qmgr
```

You can use normal `qmgr` commands. If you want to target all queues or nodes at a server use `@default` as the server name.

You can also use the commands to alter the configuration, though we would recommend running a simulation first to see how it runs through with the system configuration.

To use `pbsnodes`:

```
simsh <snapshot_directory_name> pbsnodes -av
```

For example:

```
simsh snapshot_20200708_15_54_57 pbsnodes -av
```

## 2.3.3 Running a Simulation

```
simsh <snapshot_directory_name> sim
```

For example:

```
simsh snapshot_20200708_15_54_57 sim
```

This should give some output showing how the workload ran through, e.g.:

```
Snapshot: snapshot_20200708_15_54_57
```

```
Creating usage database for fairshare.
```

```
Number of scheduling cycles run: 32
```

```
Number of jobs submitted: 0
```

```
Number of jobs run: 22
```

```
Number of jobs left over: 0
```

```
Time taken to simulate: 0
```

### 2.3.3.1 Simulation Errors

If you get a licensing error: “Error: No valid licenses found, quitting”, make sure the licensing prerequisites are met.

### 2.3.3.2 Simulation Caveats

The simulator ignores job environment variables (it does not use the value of the job’s `Variable_List` attribute).

## 2.3.4 Simulation Output

### 2.3.4.1 Output Name

By default, running a simulation on `snapshot_20200708_15_54_57` produces the result snapshot named “`snapshot_20200708_15_54_57_out`”. However, you can specify the name of the output using `sim -o <snapshot name>`.

If you don’t specify a name, when you run a simulation on a snapshot, the output is a snapshot with “\_out” appended to the name of the original. So `<snapshot_directory_name>` results in `<snapshot_directory_name_out>`.

For example, running a simulation on “`snapshot_20200708_15_54_57`” creates a snapshot named “`snapshot_20200708_15_54_57_out`”.

### 2.3.4.2 Output Contents

When you run the following:

```
simsh <snapshot> sim
```

the simulator produces these outputs:

- Number of scheduling cycles run: `<number>`
- Number of jobs submitted `<number>`
- Number of jobs run: `<number>`
- Number of jobs left over: `<number>`

These are the jobs which couldn’t be run by the simulator for reasons such as the job requests an unavailable queue or resource, or the job exceeded a limit (which might have been placed on the snapshot).

- Time taken to simulate: `<seconds>`

## 2.3.5 Reviewing Simulation Results

Review the snapshot produced by the simulation. You can use the commands listed in ["Checking Snapshot Contents" on page 5](#).

To use `qstat` to review the results created when you ran a simulation and produced `<snapshot_directory_name_out>`:

```
simsh <snapshot_directory_name_out> qstat -as1
```

For example, if the result of the simulation is “`snapshot_20200708_15_54_57_out`”:

```
simsh snapshot_20200708_15_54_57_out qstat -as1
```

## 2.3.6 Using Scheduler Logs

When you run a simulation, you can use the `sim -L` command to produce scheduler logs, which you can use to see how jobs were scheduled:

```
simsh <snapshot> sim -L
```

## 2.3.7 Modifying Your Snapshot

You can modify your simulated workload environment, to see how jobs would run in those circumstances. You modify the parent snapshot, not the output snapshot, then re-run the simulation using the modified parent snapshot. You can modify many of the characteristics of a PBS complex; we mention a few ways here.

### 2.3.7.1 Modifying Available Resources

You can change the available resources in your snapshot, such as memory, CPUs, number of execution hosts, etc. To add more nodes you edit the node configuration in the parent snapshot. To add CPUs, change the `ncpus` resource on the parent snapshot. For example, here we use `qmgr` on the parent snapshot to modify the node to have 32 cores:

```
simsh <snapshot_directory_name> qmgr -c "s n testing resources_available.ncpus=32"
```

### 2.3.7.2 Creating Nodes

You can create new nodes:

```
simsh <snapshot_directory_name> qmgr -c "c n newnode resources_available.ncpus=8"
```

### 2.3.7.3 Submitting Jobs

You can use `qsub` to submit more jobs:

```
simsh <snapshot_directory_name> qsub ...
```

### 2.3.7.4 Changing Limits

You can change limits, for example:

```
simsh <snapshot_directory_name> qmgr -c "set server max_run += [u:PBS_GENERIC=10]"
```

### 2.3.7.5 Changing Scheduler Configuration File

You can change the scheduler configuration file.

Change directory into the snapshot directory:

```
cd <path to snapshot>/sched_priv
```

Edit the configuration file named `sched_config`.

## 2.3.8 Rerunning a Simulation

To rerun a simulation:

```
simsh <snapshot_directory_name> sim
```

For example:

```
simsh snapshot_20200708_15_54_57 sim
```

## 2.3.9 Output of Rerunning a Simulation

Rerunning a simulation produces an output snapshot with the name of the parent snapshot with “\_out” appended, in addition, the previous output snapshot has been renamed with an additional “\_out” appended to it: the previous output is now at `<snapshot_directory_name_out_out>` in case you need to reference or review the results.

So if you start with a snapshot named “A”, and run a simulation on it, you get “A\_out”. But if you run another simulation on A, you get a new A\_out, and the previous output snapshot is now named A\_out\_out.

### 2.3.10 Reviewing Second Results

Review the new output snapshot, using the methods in ["Checking Snapshot Contents" on page 5](#). You can use any of the commands in ["Simulate Commands" on page 3](#).

In our example, the new output snapshot is `snapshot_20200708_15_54_57_out`, and to examine it using `qstat`:

```
simsh snapshot_20200708_15_54_57_out qstat -asl
```

You can look for changes in job run order between the accounting logs from the original and modified snapshots.

Note that `qstat -s` gives empty results because all the jobs have run through the system.
